Since the gradual removal of the doubt and the fear that have pervaded the metal business since the period July, 1909, to June, 1910, passed, the most marked point of cheerfulness has been found in the copper trade. Starting in with February of this year we have seen a steady but slow increase in price in this commodity. As a matter of fact, this rise had been anticipated by all observers. It came, however, before it was expected and has likewise been unexpectedly great. The amount of "hidden consumption" in Europe especially has, we believe, been unsuspectedly great, and it can always be laid down as a fact that in this electrical age, there cannot long be too much copper. At present this statement is most apparent, for many of the copper and brass mills of the country are working "double-turn," while the price of copper is high, yet it seems to be true that the commodity "index figure" has been fixed for some time at about 50 per cent higher than fifteen years ago. Providing this is a fact, 18-cent copper is equal to 12-cent copper in 1897. It is probable that copper will go even higher this winter for mid-summer strength usually antecedes a boom when the crops are harvested. It is doubtful, however, whether any further increase could be held for long and if copper goes up to unduly high figures, it is sure to stimulate many hidden sources of production such as the numerous "scrap" plants. This development has always occurred in the past and it is logical to expect its recurrence now. We trust that an intelligent policy of moderation will animate the copper-producers. A runaway market in copper would be the worst thing imaginable that could happen to this country. History tells us that a copper boom usually resembles the sound of the breakers on a reef.

The market for lead is, of course, equalized by the concentration of a large part of the production in the hands of one concern. Lead though the first of metals made by early metallurgical men has not increased in production recently comparably to the increase in the more difficultly reducible metals. Indeed, the production of zinc in the form of spelter and zinc pigments has now a greater annual value than that of lead.

The production of zinc has been for the last eighteen months large, totaling in the first half of the current year some 166,000 short tons. In spite of this increase, the price has steadily risen, for consumption has been larger than production. At the present time, however, this high price is likely to remain, for until the new plants are running, production cannot be increased. Any further increase is liable to be checked by imports from Europe. The great increase in consumption is believed to be in the galvanizer's demand. This is natural for with the modern tendency to build structures of an enduring nature, more iron protected with a coating of zinc is used. A great deal of spelter has also been absorbed by the brass business.

Iron and steel we find to be increasing in price and quantity. The haunting fear of a large excess of capacity over demands has had for some time a depressing influence over the minds of producer and consumer alike. As a result, we find that a policy of hand-to-mouth buying so largely prevalent for the past eighteen months has brought everything down to "hardpan." It is now seen that many of the idle plants are poorly located and so obsolete that present wage scale makes it impossible to operate them at a profit unless prices of iron and steel products would go to higher levels. Just now we witness a turning point in the iron and steel industry with prices starting to rise and with matters generally much more satisfactory to the producer. Just as sulfuric acid consumption is said to be the measure of a country's civilization so iron and steel markets are the trade barometers. The needle then points surely to fair weather.

What measure of prosperity we will have in the metal industry the next year will be found to depend on the size of the crops, on the way the ever-recurring labor troubles are handled, and on the mental balance and intelligence used by all classes of Americans, especially by the intellectual leaders. We are hopeful and optimistic enough to believe that the country is becoming saner and more sensible each year and that a period of great extravagance and inflation is not due yet. In the metal industry, it is quite plain that barring the unexpected, we will have for some time a diet of the material that Jack Sprat could not eat but that his wife could eat. This is certainly not undeserved, for a noble amount of labor and effort is used in producing metals—civilization's essentials—and the laborer is worthy of his hire.

Ten Years of an Insurgent Engineering Journal.

Ten years ago to-day the first issue of this journal was mailed from Philadelphia, to be on hand at the first Niagara Falls meeting of the American Electrochemical Society. The pleasant coincidence of this journal's tenth birthday with the issue of this International Congress number seems to justify a summing up.

It was in the spring days of the American electrochemical industries when engineering insurgency began. The same forces which made Niagara Falls the glorious center of industrial electrochemistry of the world and which brought into existence the mammoth electrolytic copper refineries around Perth Amboy and on Long Island—these same forces inspired in American electrochemists—engineers and scientists alike—the conviction that they should stand on their own feet. They should, they would, they could. And the American Electrochemical Society was founded on April 3, 1902, under brilliant auspices. It is perhaps amusing to reflect that it was in the Manufacturers' Club, of Philadelphia, a pet home of conservatives in politics, that the inaugural meeting was held, representing the first important breaking away of insurgent specialists from the big old-established engineering groups.

The enthusiasm manifested at that meeting was convincing proof that the time had arrived for the starting of an independent journal which should be the authoritative exponent of electrochemistry and electrometallurgy, the science and the art, in all its phases. Thus this journal was started as an independent publication. Its chosen name was *Electrochemical Industry* as it was to be a technical journal—a journal of applied, not of pure, science. Its first issue appeared on September 12, 1902.

From the very beginning, therefore, this journal had its own field which was not covered by any other journal. It was unhampered by precedent. The program was to conduct it along the most advanced lines of modern *technical* as distinguished from *trade* journalism.

The young journal met with a wonderfully friendly reception, even beyond the boundaries of the profession in the cause of which it was primarily enlisted. The rapid growth of the sub-

scription list and the sources from whence the new subscriptions came showed conclusively that *Electrochemical Industry* was making many friends beyond the strictly electrochemical and electrometallurgical fields. The reasons were evident.

Almost from the start, this journal had found it necessary to pass beyond the bounds of the strictly electrochemical field and to take account of new chemical and metallurgical developments with which electrochemical processes had to compete or which would react in some essential way on the electrochemical industry. Therefore, in the interest of its specifically electrochemical readers this journal had to enter a broader field.

On the other hand, as to every action there is a reaction, electrochemical developments began to be noticed more carefully by the older purely chemical and metallurgical people, at least the progressive and far-seeing among them. Much encouragement came to the journal from that side, especially from the metallurgical field. And the logical consequence was that beginning with January, 1905, the name of this journal was changed to *Electrochemical and Metallurgical Industry*.

But this was only the first stage of an evolution which has been going on ever since. A technical journal to fulfill its functions to the highest degree must grow with the industry which it endeavors to serve and must adapt itself to changing conditions. And in no branch of engineering in this country have the changes been so great in the past ten years as in the chemical and metallurgical industries.

Electrochemistry was the forerunner of these changes. The marvelous industrial triumphs of electrochemistry are still a most important phase of this evolution. Yet they represent only a single phase. The whole development is broader. In chemistry it is characterized by the rise of the chemist above the pure analyst and by the emancipation of the chemical engineer; in metallurgy by the dissociation of the metallurgical from the mining engineer.

In the olden days chemistry was a trade in the popular mind; the art of the druggist was called chemistry (and the honorable president of the Borough of Brooklyn seems to be still of the same opinion, if we understood correctly his friendly word of welcome to the Verein Deutscher Chemiker at its celebration last week). However, chemistry is now not only a glorious science, but a full-fledged engineering profession. The chemical engineer has come to his own at the side of the civil engineer, the mechanical engineer, the mining engineer, and the electrical engineer. Of course, the chemical engineer is something different from the analytical chemist or the expert in some special branch of chemical processes. Chemical engineering has to do broadly with such subjects as crushing and grinding, concentration and separation, drying and evaporating, filtration and calcination, combustion, with the measurement and control of temperatures, with chimney draft and forced draft, and with a hundred other problems which occur over and over again in any chemical plant; and, we must add at once: in any metallurgical plant.

This is the logical connection between the metallurgical and chemical sides of this journal. There is a logical community of interest between the chemical and metallurgical engineer. Managers and engineers of ore concentration plants, of smelting works of smelters and refineries, must be just as much interested in those subjects as [illegible] manufacturing chemists.

It was not always so in metallurgy. In the olden times, not so long ago, the mining engineer reigned supreme also in the smelting plant. The rich ores were chiefly worked and the metallurgical problems were few and simple. Now things are different.

Nowadays the treatment of complex and lean ores has become the rule, not the exception. The mining engineer has stepped out of the smelter and the refinery and the metallurgical engineer has stepped in, and American universities and technical schools have begun to turn out graduates fitted to develop into metallurgical and chemical engineers.

To characterize the different phases of this evolution in one phrase, it is the superseding of the rule of thumb by exact engineering principles based on the laws of physical chemistry. Chemical and metallurgical engineering becomes applied physical chemistry. That is, after all, the keynote of the whole development.

It has been the privilege of this journal to be *the* journalistic exponent of this insurgent movement in engineering. This journal has been alone in fighting the battle of the chemical engineer when he was still being ridiculed from every side. And this journal has been fighting the battle of the metallurgical engineer in his emancipation from the mining camp.

In connection with iron and steel metallurgy precisely this viewpoint led to the absorption by this journal in 1906 of the *Iron and Steel Magazine* which had advocated with highest ability the application of the methods of metallography.

Thus the evolution of this journal was strictly logical, following precisely the lines of evolution of the industries which it represents, and when it became more and more evident that it had again outgrown its name this was changed in January, 1910, to METALLURGICAL AND CHEMICAL ENGINEERING, to define precisely the field and the scope of its activities.

Whatever good this journal has done or has attempted to do in the first ten years of its career has not gone unrecognized by a generous and sympathetic public. This journal has made many friends and to its friends it is indebted for many a word and many an act of encouragement and inspiration. The results of many a work of pure love by those who are enlisted with us in the same cause have found a place in the form of articles in this journal—and, we trust, everlasting life. To all its friends this journal extends today its heartiest greetings and its deep appreciation of their unwavering support. That it has also made some enemies goes without saying; only the head waiter of a Broadway hotel can afford to have no enemies. That comes with fighting. And a journal that endeavors to mirror and foster an insurgent movement must fight.

To sum up, this journal was founded ten years ago at the psychological moment. With its individuality METALLURGICAL AND CHEMICAL ENGINEERING has a right of existence, based not on a theory, but on a condition—on an actual, live condition in the intellectual, industrial, economic development of this country. This is the foundation of its hold on the industries which it endeavors to serve, and this is the foundation of the claim which we think it has on the sympathy of all who, whether they are with us or not, at least recognize the right of a journal that fights its cause independent and unafraid.

Events Preceding the Congress

The Celebration of the Verein Deutscher Chemiker The International Congress for Testing Materials Dr. Howe's Presidential Address Local Functions

The center of the pre-congress activity was the Chemists' Club, where innumerable committee meetings were held and many pleasant private lunches and dinners were given to those who formed the advance guard of the foreign delegates. Of the larger official receptions the first one—that of the Society of Chemical Industry—was held at the Chemists' Club on the evening of Saturday, August 31.

On Monday, September 2, however, the real work began. The Verein Deutscher Chemiker held a meeting at Havermeyer Hall, Columbia University, which was opened by the President, Geheimrat Dr. CARL DUISBERG, who addressed the meeting at the announced hour with a little humorous speech, remarking that he could quote the German poet's lines: "Wer zählt die Völker, nennt die Namen, die gastlich hier zusammenkamen"—if it wasn't for the fact that the bulk of the German chemists arriving on the steamships *Cleveland* and *George Washington* were still in Hoboken, as these two steamers were only landing that morning. They arrived later during the session, and at the conclusion of the meeting the attendance was somewhat like 400. In the whole the German delegation to the Congress numbers 150, besides some 50 ladies.

Verein Deutscher Chemiker

Dr. Duisberg explained that the Verein Deutscher Chemiker had been founded in Frankfort in 1887 by 12 German chemists. From small beginnings it has now grown into the largest German chemical society, the number of members being 5000. The twenty-fifth anniversary of the foundation of the society was celebrated this spring in Freiburg, and the meeting at Columbia University was intended as a continuation of this twenty-fifth anniversary celebration, in honor of the New York local section of the Verein Deutscher Chemiker.

On behalf of the Mayor of New York, the President of the Borough of Brooklyn, Mr. Speer, welcomed the Verein to New York.

Dr. Chas. F. Chandler, speaking for the American Chemists, made a delightful little address of welcome in German.

Prof. Wegscheider of Vienna spoke quite eloquently for the Austrian chemists.

Two telegrams of welcome were then officially approved and sent. One to President Taft and the other to the German Emperor.

The professional session followed, in which two papers were read. The first paper was presented by Dr. F. RASCHIG, on the scientific and technical importance of tarphenols. Dr. Raschig spoke exceedingly well, giving a concise sketch of the leitmotiv in the evolution of the tarphenol industry. The different stages of the evolution were brought out with greatest clearness, and the remarks were even not without some slight piquancy when at the conclusion of his address he discussed the structural formula of bakelite. The second address was made by Dr. F. W. FREERICHS of St. Louis, Mo., who gave a sketch of his 30 years of hard work and success as a German chemist and manufacturer in the United States.

On the same evening a commers was held by the Verein Deutscher Chemiker at Arion Hall. Dr Schweitzer presided. There were a great many addresses, all being very well received. There were many salamanders and there was a "Bierspiel" full of Teutonic humor. The large hall was crowded and the whole commers had "real go" and will long be remembered by those who attended it.

On the same day, Monday, September 2, the Sixth International Congress for Testing Materials started. Of course, it deserves a report for itself, independent of the Congress of Applied Chemistry. This will be given in our regular October issue. At this place only the opening of the Congress and the general arrangements will be noticed. The sixth congress of the International Association for Testing Materials was formally opened on the morning of September 3 in the Engineering Societies Building in New York. There were about 400 members present, representing 27 countries. The convention was called to order by Capt. Robert W. Hunt, president of the American Society for Testing Materials, who welcomed the members in the name of that organization, which is affiliated with the association. He referred to the fact that the death of Dr. Charles B. Dudley had been followed by the appointment of Dr. Henry M. Howe by the executive committee as acting president of the Congress, the constitution of that body making it necessary for the Congress itself to elect a permanent president.

Congress for Testing Materials

Director A. Martens of the Royal Testing Laboratory at Gross Lichterfelde was then introduced, who announced that, the formalities of the constitution having been observed, Dr. Howe would take charge of the meeting.

Brig.-Gen. William H. Bixby, Chief of Engineers, U. S. A., was introduced as the representative of President Taft, and spoke in both French and English.

Governor John A. Dix welcomed the Congress in the name of the State of New York.

Controller Prendergast extended a welcome in behalf of the City of New York. He gave a brief but very interesting summary of the enormous sums spent by the city, since the act of consolidation enlarging its boundaries, for public buildings, parks and playgrounds, streets, bridges, and other public works, amounting in all to many hundreds of millions of dollars. He then referred to his surprise on taking office to learn that there were few standard specifications for materials, and that different city departments were paying different prices for precisely the same materials. So he undertook, with the help of the Board of Estimate and Apportionment, to standardize requirements and inspection, and one of the means of doing this was the opening of a municipal testing laboratory, not much of an establishment yet, but full of the promise that rests upon successful achievement so far as its opportunities have extended.

Dr. HENRY M. HOWE's presidential address was scholarly and most interesting. He reviewed the importance of the testing engineer's work and the value of the Congress. In order to specify proper tests, it is first necessary to determine what are the most trying conditions to which a structure may be subjected, and these data are too often assumptions rather than actual facts. Having determined these conditions it is necessary to devise a test to reproduce them, but many tests in use to-day do not accomplish this, and in that respect they are unfit. Another objection to present practise is that many tests are carried to destruction, and so must be made on small samples instead of on objects which go into service. The number of physical properties which offer themselves as possible means of testing is very great, and among them may be found some lending themselves to indestructive tests which may be made on the materials which are actually put into use. "The facts that such relatively modern marvels as the reciprocating engine and the Bessemer process seem already threatened, and that the electric telegraph has already yielded much of its importance to the telephone and to radio-

Dr. Howe's Presidential Address

telegraphy, may help us to a right attitude, in which we concede that as to-day's makeshift testing methods are sure to be displaced some day by some new ones, the new ones offered to-day may be those which are to displace them."

In referring to the present status of the International Association for Testing Materials, Dr. Howe stated that it includes now 30 countries, and that the membership has grown to 3700.

Sectional Sessions

The professional work of the Congress for Testing Materials was carried out by three sections. Section A was devoted to metals, Section B cement, stone and concrete, Section C to wood, oil, bitumen, rubber and other materials. They began their sessions on the afternoon of September 3. In the whole eighteen sessions were held. There was a formal reception of the members of the Congress for Testing Materials and their guests on the evening of September 2 at the Engineering Societies Building. This was tendered by the American Society for Testing Materials, the American Institute of Electrical Engineers, the American Society of Mechanical Engineers and the American Institute of Mining Engineers.

On the evening of September 3 the New York Public Library was visited under the guidance of officials of the city and on the afternoon of September 4 a steamboat trip was made to the Military Academy at West Point.

On the evening of Saturday, September 7, the members of the International Congress for Testing Materials joined the members of the International Congress of Applied Chemistry to follow an invitation of the American Chemical Society for a highly enjoyable reception at the Metropolitan Museum.

On Tuesday, September 3, the Society of Chemical Industry held its business and annual meeting at the Chemists' Club, where the address of the retiring president, Dr. Rudolph Messel, was presented.

On the evening of Tuesday special trains took the foreign delegates to the Congress of Applied Chemistry, together with quite a number of Americans, to Washington, for the formal opening of the Congress of Applied Chemistry.

Formal Opening of the Eighth International Congress for Applied Chemistry

Inaugural Meeting—Reception by the President

Official Opening in Washington

The Eighth International Congress of Applied Chemistry was officially opened at Continental Hall, Washington, D. C., on September 4, 1912, at 11 o'clock. Dr. Wm. H. Nichols, the president of the Congress, expressed the regrets of President Taft that he could not open the Congress personally on account of a sprained ankle. He introduced Dr. E. W. Morley, honorary president of the Congress, who spoke o the rapid strides American science has made in a comparatively short time. European nations had already made wonderful advances in chemistry at the time of the discovery of America. America was at first too busy building up a nation to study chemistry, but now it has become different.

Dr. Nichols spoke of the object and work of the Congress in his characteristic jovial manner, which made all foreign delegates feel right away at home.

Then came the official responses of the representatives of the different countries. At the end of each speech the national hymn of the country represented by the speaker was played and the whole audience rose.

Speeches of Foreign Delegates

Prof. Dr. Rudolf Wegschneider spoke for Austria. He spoke in German and ended with a few exceedingly pleasant remarks in English. He said that the American chemists in the last 100 years had built up their science and industry as successfully as European countries had done in 2000 years. Prof. L. Lindet spoke for France, Prof. Dr. von Buchka for Germany, Sir William Ramsay for Great Britain. He said that while the trip over the water was a long one "blood was thicker than water," and in expressing his gratitude for the hearty welcome he quoted the old definition that "gratitude is a lively sense of favors to come."

Dr. Jokichiro Lemori spoke for Japan, Commanditore Giacome Ciamician for Italy, Prof. P. Walden for Russia. Prof. Walden made an excellent speech in German, and in summing up the present situation of chemistry he quoted the old words of Hutten, "Es ist ein Lust zu leben."

Dr. Samuel Eyde of Norway spoke for the other countries, and made a hit by the remark that in 1001 Lief Ericsson landed at Martha's Vineyard and founded the first chemical factory in America—for the manufacture of wine.

At the conclusion of the meeting two resolutions were presented.

Dr. Wiley, who was received with friendly applause, presented a resolution of thanks to the Daughters of the American Revolution for the permittance to use the Continental Hall for the opening meeting.

Then Dr. David T. Day moved that one copy of the official Congress badge be struck in pure gold. The motion was seconded by Dr. Kunz, and after it had been carried the pure gold badge was presented by Miss Day to the President of the Congress, Dr. Nichols.

Reception by President Taft

In the afternoon there was a reception at the White House, when President Taft, who had especially come for this occasion from his summer home in Beverly, Mass., welcomed the members of the Congress. The members had assembled in the East Room of the White House, when President Taft, unable to walk on account of his sprained ankle, was wheeled in on a wicker chair. President Taft then made the following speech of welcome:

"Mr. Chairman, and Ladies and Gentlemen of the International Congress of Applied Chemistry:

"I have much pleasure in welcoming you on behalf of the government and the people of the United States, to Washington. I sincerely hope that your stay in this capital may be an agreeable one.

"Yours is one of those important international congresses that mark the great progress which has been made in research and application of newly discovered principles in a most important science and art. If there be any science that goes to the heart of the matter it is chemistry. Dealing with atoms and molecules and their associations, and the manifestations of their action upon each other, chemistry seems at one time the most abstruse of sciences, and then when we see it applied in the great modern factories of Germany and other countries in the manufacture of those elements which are essential to the success of the industrial arts, we are made to know that the scope of the science from the theoretical to the practical is wider than that of any other."

President Taft then made some very interesting extemporaneous remarks on the patent question. He said that various

sections of the Congress would discuss different questions not peculiarly chemical, especially the question of patents what patents ought to include and what kind of a patent system ought to be adopted by each government. Patents have played a very great part in the development of the United States, and there is given to patentees a very valuable monopoly for the purpose of discovering by their industry new methods of accomplishing useful results. Whether we have made this monopoly too great or not is now the subject of consideration by a commission provided for by Congress. There is certainly great room for improvement in the machinery of our Patent Office, and it would be well if more value could inhere in the issuing of a patent as an evidence of real property. Some remarks on long-drawn-out litigations and on the work of patent lawyers and patent experts were added.

After the President had finished his speech there were three very hearty cheers for him and then the President asked the members of the party to "adjourn to the backyard of the White House," where he would be glad to receive and shake hands with all the members personally. This lawn party proved to be an exceedingly pleasant affair. After the President had been wheeled out he greeted everyone in the long line of those to be received with a pleasant word and a hearty handshake. The reception lasted from 5 to 6:30. The U. S. Marine Band played near the south entrance to the White House and refreshments were served in special tents.

The Lawn Party

In the evening there were various private dinners and a reception by the regents and secretary of the Smithsonian Institution was held at the New National Museum. This was a very brilliant affair.

During the next day visits were paid to the various Government bureaus and institutions and other places of interest in Washington.

The New York Meeting of the Congress.

Report of the Sessions of the Twenty-four Sections.

The real work of the Congress began after the return of the delegates from Washington to New York. It will be well to state at this place the organization of the Congress. Dr. William H. Nichols is the president of the Congress, Dr. Edward W. Morley the honorary president, Dr. Bernard C. Hesse the secretary, and Mr. Wm. J. Matheson the treasurer. These four officers, with an executive committee, were responsible for the general arrangements of the Congress as a whole. The professional sessions of the Congress were held in 24 different sections as follows:

Organization of the Congress

Section I.—*Analytical Chemistry.*

President, Dr. W. F. Hillebrand; Vice-President, Dr. H. P. Talbot; Secretary, Dr. Ellwood B. Speer.

Section II.—*Inorganic Chemistry.*

President, Dr. Chas. L. Parsons; Vice-President, Dr. Charles Baskerville; Secretary, Dr. Arthur L. Day.

Section IIIa.—*Metallurgy and Mining.*

President, Dr. Joseph W. Richards; Vice-President, Dr. John B. Francis Herreshoff; Secretary, Mr. Walter S. Landis.

Section IIIb.—*Explosives.*

President, Dr. Charles E. Munroe; Vice-President, Dr. Thomas M. Chatard; Secretary, Dr. Walter O. Snelling.

Section IIIc *Silicate Industries.*

President, Dr. Allerton S. Cushman; Vice-President, Mr. Karl Langenbeck; Secretary, Mr. Zoltan de Horvath.

Section IV.—*Organic Chemistry.*

President, Dr. Marston T. Bogert; Vice-President, Dr. William A. Noyes; Secretary, Prof. Harry L. Fisher.

EDWARD W. MORLEY, HONORARY PRESIDENT EIGHTH INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY.

WM. H. NICHOLS, PRESIDENT EIGHTH INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY.

Section IVa.—*Coal Tar Colors and Dyestuffs.*

President, Dr. Herman A. Metz; Vice-President, Mr. Eugene Merz; Secretary, Dr. Gustav P. Metz.

Section Va.—*Industry and Chemistry of Sugar.*

President, Dr. W. D. Horne; Vice-President, Dr. F. G. Wiechmann; Secretary, Dr. C. A. Browne.

Section Vb.—*India Rubber and Other Plastics.*

President, Dr. L. H. Baekeland; Vice-President, Mr. C. C. Goodrich; Secretary, Mr. Jasper E. Crane.

Section Vc.—*Fuels and Asphalt.*

President, Dr. David T. Day; Vice-President, Dr. F. Schniewind; Secretary, Mr. Edward W. Parker.

Section Vd.—*Fats, Fatty Oils and Soaps.*

President, Dr. David Wesson; Vice-President, Dr. Martin H. Ittner; Secretary, Mr. L. M. Tolman.

Section Ve.—*Paints, Drying Oils and Varnishes.*

President, Dr. Maximilian Toch; Vice-President, Mr. Gustave W. Thompson; Secretary, Dr. Parker C. McIlhiney.

W. J. MATHESON, TREASURER EIGHTH INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY.

Section VIa. *Starch, Cellulose and Paper.*

President, Dr. A. D. Little; Vice-President, Dr. T. B. Wagner; Secretary, Mr. C. C. Moore.

Section VIb.—*Fermentation.*

President, Dr. Francis Wyatt; Vice-President, Dr. Robert Wahl; Secretary, Mr. Emil Schlichting.

Section VII.—*Agricultural Chemistry.*

President, Dr. Frank K. Cameron; Vice-President, Dr. H. J. Wheeler; Secretary, Dr. J. A. LeClerc.

Section VIIIa.—*Hygiene.*

President, Dr. W. P. Mason; Vice-President, Prof. C. E. A. Winslow; Secretary, Mr. Daniel D. Jackson.

Section VIIIb.—*Pharmaceutical Chemistry.*

President, Prof. Joseph P. Remington; Vice-President, Dr. V. Coblentz; Secretary, Dr. George D. Rosengarten.

Section VIIIc.—*Bromatology.*

President, Dr. W. D. Bigelow; Vice-President, Dr. A. L. Winton; Secretary, Dr. E. M. Chamot.

Section VIIId.—*Physiological Chemistry and Pharmacology.*

President, Dr. John J. Abel; Vice-President, Dr. William J. Gies; Secretary, Dr. John A. Mandel.

Section IX.—*Photochemistry.*

President, Dr. W. D. Bancroft; Vice-President, Mr. R. James Wallace; Secretary, Mr. E. J. Wall.

Section Xa.—*Electrochemistry.*

President, Dr. William H. Walker; Vice-President, Prof. C. F. Burgess; Secretary, Dr. E. F. Roeber.

Section Xb.—*Physical Chemistry.*

President, Dr. W. R. Whitney; Vice-President, Dr. Alexander Smith; Secretary, Dr. Arthur B. Lamb.

Section XIa.—*Law and Legislation.*

President, Chief Justice Edward D. White; Vice-President, Dr. William L. Dudley; Secretary, Mr. John C. Pennie.

Section XIb.—*Political Economy and Conservation.*

President, Dr. J. A. Holmes; Vice-President, Dr. C. R. Van Hise; Secretary, Dr. Charles A. Davis.

FRIDAY AND SATURDAY SESSIONS.

Section of Electrochemistry.

The first meeting of the Section of Electrochemistry was held on the afternoon of Friday, September 6, and was opened by the President of the Section, Dr. Wm. H. Walker.

The first paper was presented by Dr. Fink.

Ductile Tungsten.

The paper by **C. G. Fink,** of the General Electric Company, Harrison, N. J., dealt with the applications of ductile tungsten, of which large quantities of drawn wire, flexible and strong, are being daily produced for the manufacture of incandescent lamps.

The ductile metal is practically insoluble in all of the common acids, its melting point is higher than that of any other metal, its tensile strength exceeds that of iron and nickel, it is paramagnetic, it can be drawn down to smaller sizes than any other metal, and its specific gravity is 70 per cent higher than that of lead. It was natural that a metal with such striking properties as these should soon find application other than that for incandescent lamps.

Wrought tungsten has been substituted with success for platinum and platinum-iridium as *contact points* in spark coils, voltage regulators, telegraph relays, etc. The service far exceeds that for platinum and platinum-iridium contacts due to the greater hardness, higher heat conductivity, and lower vapor pressure of tungsten as compared with platinum.

Electric laboratory furnaces with tungsten resistors are of two types. In one a tungsten wire is wound on an aluminum tube in an air-tight box with a hydrogen atmosphere.

In the second type a tungsten metal tube takes the place of the helical carbon resistor in an Arsem vacuum furnace.

Tungsten gauze is used successfully for separating solids from acid liquors in the laboratory. This gauze could well be used on a commercial scale, for example: for the removal of sludge from copper refining baths, and for centrifugal apparatus in general whenever acid liquids or acid gases are dealt with. Furthermore, it might be used in apparatus such as described by Cottrell for the removal of sulphuric mist from gases.

Wrought tungsten targets for Roentgen tubes have proved to be one of the most interesting applications.

For thermo-couples the tungsten-molybdenum couple is not less interesting. The electro motive force increases with the temperature up to about 540 deg. (12½ millivolts) then decreases and passes through o millivolts at about 1300 deg. This couple is very convenient for high-temperature measurements in the tungsten-hydrogen furnace.

For standard weights tungsten is also well suited, since wrought tungsten can be made so hard that it will readily scratch glass and still be ductile; furthermore, the density is high (19.3 to 21.4) and it is unaffected by the atmosphere. Tungsten weights remain wonderfully constant.

Besides the applications of tungsten cited above, many others have been but partly worked out and others merely suggested. Owing to its chemical stability the finest sizes of wire down to 0.0002 in. or 0.0005 mm. in diameter, are well adapted for galvanometer suspensions and for cross-hairs in telescopes. It has also been suggested to use these fine wires in surgical operations in place of the coarser gold and silver wires. A further suggestion is the use of the wire in musical instruments.

Acid-proof dishes and tubes have been made out of tungsten; furthermore, tungsten wire recommends itself as a unit resistance since it can be made absolutely pure, can be easily duplicated and is not corroded.

Since tungsten is paramagnetic and elastic, it is being tried out in electrical meters, replacing the phosphor-bronze springs. Similarly watch springs could be made which would never become magnetized. Finally tungsten pen points, tungsten draw-

ing dies, tungsten knife blades, tungsten reinforced asbestos curtains and fireproof coverings, etc., were mentioned.

TABLE OF PHYSICAL AND CHEMICAL PROPERTIES OF DUCTILE TUNGSTEN.

Density ..... 19.3 to 20.2
Tensile strength..... 322 to 427 kg. per sq. mm.
Youngs modulus of elasticity 42.200 kg. per sq. mm. (Steel 20.000).
Melting point 3177 (Langmuir), 3100 to 60 (v. Pirani & Meyer).
Boiling point 3700 deg.?
Thermal conductivity 0.35 gram cal. per cm. per sec. per 1 deg. (Pt 0.166).
Expansion coefficient 4.3 x 10^{-6} (Pt 8.8 x 10^{-6}).
Specific heat 0.0358 (Weiss).
Resistivity hard: 6.2 microhms per cu. cm. and annealed, 5.0 microhms per cu. cm.
Temperature coefficient of resistance 0.0051 (0°-170°).
Magnetic susceptibility 10.33 (Honda) i.e. paramagnetic.
Hardness 4.5 to 8.0 (Mohs scale).
Insoluble in HO_1, H_2SO_4? HNO_3?, HF? NaOH, KOH (aq), $K_2Cr_2O_7$, H_2So_4. Soluble in mixtures of HF and HNO_3, and in fused nitrates and peroxides.

The boiling point of the metal has not yet been determined.

In the discussion Dr. Amberg asked whether the alloys of tungsten could also be made ductile, as this might be of great commercial importance. Dr. Fink replied that they had studied various alloys and had found that what was true of tungsten was also true of its alloys. They had not studied the alloy in which Dr. Amberg was most interested, namely, ferro-tungsten.

BERNHARD C. HESSE, SECRETARY EIGHTH INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY.

In reply to a question as to the cost of the metal, Dr. Fink said that the cost of the crude tungsten metal is twice that of crude nickel, while the cost of pure tungsten is between $10 and $12.

Alundum as a Refractory Material.—A paper by **P. A. Boeck,** of Worcester, Mass., refers to the use of alundum (fused alumina and originally employed for abrasive purposes only) for the manufacture of chemical laboratory articles. This is done by crushing the alumina, grading to a uniform mesh, and mixing with a small amount of a highly refractory ceramic bonding material, shaping by casting or molding and burning at a high temperature in a porcelain kiln. According to the researches of L. E. Saunders fused alumina has the following properties:

It is between 9 and 10 in the scale of hardness, has a melting point of 2050 deg. C., and a thermal conductivity of 2.1 times that of fireclay.

The electrical conductivity of a sample at various temperatures was:

At 520 deg. C., 130. megohms.
At 730 deg. C., 16. megohms.
At 892 deg. C., 5.3 megohms.
At 1020 deg. C., 1.8 megohms.

The specific heat between 20 deg. C. and 100 deg. C. is 0.198. Being neither strongly acid nor basic it is not chemically active even at elevated temperatures. The thermal conductivity has been found to be a linear function with a temperature coefficient of 0.0000078 per degree centigrade. It can be made with a maximum tensile strength of 1700 per square inch and the porosity of the various mixtures can be changed to suit the requirements which allows it to be used for filtration purposes.

Its practical use has been for linings of electric furnaces of the wire resistance type, muffles, tubes, cores, and other shapes. Refractory crucibles for melting platinum and for standardizing thermocouples, combustion boats for the determination of carbon in steel, and similar work have been repeatedly used. Nonporous pyrometer tubes for high-temperature work, refractory cement, porous extraction thimbles, filtering crucibles and cones for analytical work, filtering plates, dishes, etc., have been made of this material and have the advantage of being highly refractory, having a high thermal conductivity, being chemically inactive and being of easily controlled porosity and composition for any particular purpose.

Bicalcic Phosphate Fertilizers.

"The method of producing bicalcic phosphate with the help of electrolytically produced acid and alkali" was the title of a paper presented by **Prof. W. Palmaer,** of the Institute of Technology, Stockholm, Sweden.

Acid phosphate, basic slag, bone meal, bicalcic phosphate are the chief phosphate fertilizers in the order of the amount produced.

The annual output of acid phosphate amounts now to some 10 000 000 tons.

Bicalcic phosphate so far has been produced only in small quantities, and this product has so far been obtained only as a by-product in the manufacture of glue, *i. e.,* in the process when bone is soaked in diluted hydrochloric acid, whereby the main product in the manufacture, the glue substance, remains undissolved, while a solution of bone phosphate is obtained as a by-product.

This is turned to account by precipitation with lime, by which means bicalcic phosphate is obtained.

On the other hand, it is a long while ago since it was first proposed to obtain bicalcic phosphate as the chief product from every kind of raw phosphate in the same way, viz., by extracting the raw phosphate with hydrochloric acid and precipitating the solution thus obtained with lime. This method would have the advantage that one could make use of very poor and otherwise valueless raw phosphate, provided it does not contain too large a proportion of any useless, soluble compound, such as carbonate of lime. In the production of acid phosphate, on the other hand, one cannot utilize raw phosphate with a lower percentage than about 50 per cent bone phosphate, since owing to the admixture of gypsum the percentage in the acid phosphate of available phosphoric acid is only about half that of the raw phosphate's percentage of phosphoric acid, and consequently consideration of freight charges for the prepared article excludes the use of a raw material in which the percentage is low.

However, it has been found that the price of hydrochloric acid has been too high for the adoption of this method. This, in its turn, is due to the fact that the production of hydrochloric acid according to the old methods entailed the sacrifice of sulphuric acid.

But the case is different if the acid is produced in such a way that a suitable salt, for instance, perchlorate of sodium is electrolyzed with a diaphragm, so that free acid is generated in the anode chamber, and a solution of caustic alkali in the cathode chamber. With a tension of 4½ volts and 80 per cent current efficiency the production of the kilogram equivalent of acid requires 182 hp-hours, whereby the alkali necessary for the precipitation of the bicalcic phosphate is obtained at the same time without additional cost in the cathode chamber. If 1 electric horse-power can be obtained for $10 a year the cost of the equivalent of 1 kg. of acid is about 24 cents, the alkali being obtained at the same time, while with the old method lime had to be purchased. There is no outlay for material beyond what is caused by spilling, etc., as the electrolyte regenerates, as will be seen from what follows.

If the price of 1 ton of chamber acid with 65 per cent H_2SO_4 is $5, the cost of the equivalent of 1 kg. of H_2SO_4 (49 kg.) is about 38 cents.

This calculation consequently shows that, provided the remaining outlay for the electrolytic process can be kept within reasonable limits, it should be assured of success, especially as it allows of the utilization of otherwise valueless raw phosphate or refuse.

This calculation was the basis of the author's investigations, the object of which was consequently to try to make the method economically feasible, chiefly by finding a suitable electrolyte, and by constructing a serviceable electrolyzer.

As in the process there is no consumption of chemicals, beyond loss by spilling, etc., the cost of the sulphuric acid used in producing acid phosphate is replaced by the cost of the electric power. The economic result of the method depends therefore in the first place on the price of the power.

General Features of the Method.—A solution of chlorate or perchlorate of sodium is electrolyzed. In the anode chamber an acid is thereby generated—chloric or perchloric acid—and in the cathode chamber a solution of caustic soda. The electrolysis is continued until a certain quantity of the dissolved salt has been separated into acid and alkali. The anode and cathode solutions are led off into separate receivers. The

ARTHUR D. LITTLE, PRESIDENT AMERICAN CHEMICAL SOCIETY

acid anode solution is then allowed to work in a dissolving battery upon raw phosphate, in which process the phosphate is dissolved.

Into the solution thus obtained the alkaline cathode solution is introduced, the whole being meanwhile kept vigorously stirred, until the liquid bears evidence of a slightly acid reaction; to obtain that result about half the cathode solution is required. In the process bicalcic phosphate is precipitated as a finely crystalline precipitation, which is drained off by filtration and washed. The filtrate, which contains one-third of the lime originally dissolved, but hardly any phosphoric acid, now has added to it the remainder of the cathode solution, which has previously been saturated with carbonic acid from fuel-gas. The lime is precipitated as carbonate, which is allowed to settle. The solution remaining above is then drawn off The original electrolyte is regenerated by its means and again enters the electrolyzing apparatus.

The Nature of the Electrolyte.—As electrolytes, solutions of perchlorate of sodium or chlorate of sodium are suitable, or else mixtures of those salts, the presence in small quantities of other salts, for instance, chlorides, being of no account. Produced by electrolysis, both these salts may be had at reasonable prices.

Perchlorate of sodium is an ideal electrolyte for the purpose in question. On electrolyzing its solution with a diaphragm, sodium hydrate is formed in the cathode chamber and perchloride acid in the anode chamber, while hydrogen is developed at the cathode and ozonic oxygen at the anode. No noticeable reduction of the salt occurs at the cathode, nor any other change, and the solution of perchloric acid obtained is perfectly constant at such temperatures as are likely to occur in the electrolyzing (maximum 50 deg. C.). Furthermore, the salt is exceedingly easily soluble (deliquescent) and thus easy to wash away.

Chlorate of sodium is less constant, in that the chloric acid solution formed in the anode chamber already begins to decompose at 40 deg. C., free chlorine being developed. Moreover, it is considerably reduced at the cathode to chloride. But the principal change is that the development of oxygen at the anode almost ceases, because the chlorate there is oxidized to perchlorate. For this reason a start can very well be made with chlorate of sodium, since though the drawbacks mentioned (the decomposing of the chloric acid and the reduction of the chlorate) appear at first, they soon disappear, viz., when the chlorate has become perchlorate of sodium. Even if the start is made with chlorate of sodium, the electrolyte consists after a while of pure perchlorate, which, as has been said, suffers no further change.

The Electrolysis.—The voltage amounts on the average to 4.5 volts per cell, including loss in connections.

In a diaphragm process, where the new substances formed at the cathode and the anode remain in the solution (in this case alkali, or perchloric acid), the current efficiency continually diminishes, of course, in proportion as the newly formed substances begin to take part in the current-circuit. The author's general practice is to provide solutions with 1 gram equivalent of acid or alkali per liter, and have then a current efficiency of 82 per cent and a ballast of undecomposed salt in both acid and alkali solutions.

Raw Material.—Of course, the high percentage raw phosphates used to make acid phosphate can be employed for the process, but it is not for such, but rather for low-percentage raw phosphates, at present worthless or of inferior value, that the process is primarily designed. For instance, low-percentage apatites and apatite waste, waste from magnetic separation of phosphoric iron-ore, and certain low-percentage phosphorites.

As the process consists in dissolving the bone phosphate occurring in raw phosphate, and then precipitating bicalcic phosphate from the solution, the product obtained will always be of the same nature, irrespective of the percentage of the raw phosphate. Raw products have been employed whose percentage of bone phosphate varied between 20 per cent and 88 per cent.

Futhermore, the raw phosphate need not be finely pulverized, provided that the bone phosphate is not embedded in insoluble minerals and that other soluble substances, such as

certain silicates, do not occur in too great a quantity. The author has worked with material of as coarse crushing as 5 cm.

Assuming that the solution of bone phosphate is effected according to the formula

$$Ca_3P_2O_8 + 6HClO_4 = 3Ca(ClO_4)_2 + 2H_3PO_4$$

then per liter of 1 — normal acid 23.7 grams of phosphoric acid should be dissolved. However, experience has shown that it is necessary to assume a somewhat lower figure, say, 20 gr. P_4O_5 or 43.6 gr. $Ca_3P_2O_8$ per liter of 1 — normal acid. This figure holds good provided that no other bodies soluble in acids occur in the raw phosphate.

W. LASH MILLER, PRESIDENT AMERICAN ELECTROCHEMICAL SOCIETY.

Of such, calcium carbonate readily and completely dissolves in acids. One per cent of CO_2 in the raw phosphate causes approximately the same consumption of acid (or of energy) as 1 per cent of P_2O_5, without giving any product of any value to speak of. A raw phosphate which contains 20 per cent of P_2O_5 (as $Ca_3P_2O_8$) and 2 per cent of CO_2 (as $CaCO_3$) consequently requires about 10 per cent more energy than a raw phosphate with the same proportion of phosphoric acid, but free from carbonate of lime.

Iron oxides (iron-ores), on the other hand, are only dissolved very slightly.

Most silicates are insoluble in diluted acids. However, silicates may occur, e. g., together with apatite, which are easily soluble that they dissolve to a noticeable degree if the acid is in contact with them for any length of time after most of the phosphate is dissolved. Attention must be paid to this in the course of the lixiviation, and the work regulated accordingly.

As regards the utilization of the bone phosphate in the raw material, it is possible to count upon extracting 98 per cent of it, sometimes more, sometimes a little less, viz., when easily soluble silicate is present.

Precipitation of the Bicalcic Phosphate and Calcium Carbonate.—To precipitate the bicalcic phosphate, the solution of caustic soda obtained by electrolysis is introduced into the phosphate solution by means of a sprayer.

The employment of the soda solution as a precipitator, instead of lime-white, has a considerable advantage. For the fact is that as soon as the solution has become alkaline at any point, bone phosphate is precipitated there instead of bicalcic phosphate. This once precipitated bone phosphate is only slowly converted into bicalcic phosphate, even if the average acidity of the liquid is such than only bicalcic phosphate ought to occur. At least a portion of the bone phosphate thus formed remains therefore in the precipitate bicalcic phosphate. The bone phosphate thus precipitated is very finely distributed, it is true, and is even soluble after drying in 2 per cent citric acid; but it has no manuring value worth speaking of. The phosphoric acid precipitated as bone phosphate, must therefore be looked upon as lost.

It is clear that it would be much easier to avoid the formation of bone phosphate if a sodium hydrate solution, distributed in jets, were employed as the precipitator, than if lime-white were used, since in the latter case we get particles of solid calcic hydrate, round which the solution easily becomes alkaline.

Experience also proves that in employing sodium hydrate, which is added until the phosphate solution is still very slightly acid or only just neutral, bicalcic phosphate can be precipitated so completely that only 0.1 to 0.2 per cent of all the phosphoric acid remains unprecipitated, while 98 per cent of the phosphoric acid in the bicalcic phosphate is soluble in citrate, and thus only 2 per cent of the phosphoric acid is present as bone phosphate.

The precipitated bicalcic phosphate, which is microcrystalline, is filtered off, washed and dried. It thus forms a light, pure white powder, and its proportion of citrate-soluble phosphoric acid amounts to from 35-38 per cent, according to the completeness of the drying.

Since about 2 per cent of the phosphoric acid in the raw phosphate is left behind in the extraction, and no quantity to speak of remains unprecipitated, and about 2 per cent is recovered as precipitated bone phosphate, about 96 per cent of all the phosphoric acid in the raw phosphate is extracted in the process as valuable citrate-soluble phosphoric acid.

The bicalcic phosphate obtained shows, even if it contains iron and aluminium phosphate, no retrogradation of soluble phosphoric acid, which is simply due to the fact that it can be perfectly dried, after which no conversion can take place. On the other hand, retrogradation shows itself in damp acid phosphate.

From the filtrate of the bicalcic phosphate is precipitated, the lime that remains in the solution, together with the rest of the sodium hydrate solution, after the latter has been saturated with carbon anhydride from fuel-gas, as carbonate of lime, which can be used as a fertilizer or in chemical workshops.

Its mass corresponds to about one-fourth of the weight of the bicalcic phosphate obtained if the raw product used be free of carbonate. If calcium carbonate occurs in the raw product the mass obtained in the process will be proportionately increased.

Power Expenditure.—From the statements given above it follows that the electric horse-power (direct current) per year of $350 \times 24 = 8400$ hours produce 2.24 tons of bicalcic phosphate with 35 per cent of citrate-soluble phosproric acid, if free of carbonate. If a 38 per cent article is produced 2.06 metric tons per hp-year will be obtained, etc.

Value of Bicalcic Phosphate Fertilizer.—The author finally refers to the careful experiments extending over many years of Prof. H. G. Soderbaum, agricultural chemist at the Central Institution for Experimental Agriculture, Stockholm, partly by Dr. Hj. von Feilitzen, director of the Swedish Peat Society, Jonkoping, Sweden.

The result of the experiments in cultivation is that the citrate-soluble phosphoric acid in the bicalcic phosphate proves to possess the same fertilizing value as the water-soluble phosphoric acid in the superphosphate, and consequently the same value as a trade product. That result might, indeed, have been foreseen, inasmuch as it is probable that the superphosphate in the soil is rapidly transformed into bicalcic phosphate through the agency of the compounds of lime present there. This result is supported by the trials carried out by practical agriculturists, who are well satisfied with both the results of the phosphate and its qualities in general. Owing to its high

percentage the freight charges are low for the valuable ingredient, and a very small amount need be manipulated by the farmer. It is in all other respects easy to handle and does not damage the sacks in the least.

The merits of the electrolytic method are as follows:

It admits of the use of cheap low-percentage raw phosphate, not available for the superphosphate industry.

By it a phosphate containing 35.38 per cent soluble phos-

L. H. BAEKELAND, PRESIDENT AMERICAN INSTITUTE OF CHEMICAL ENGINEERS.

phoric acid is obtained, even from low percentage raw material.

Freightage for a given quantity of phosphoric acid in the finished article is only about half that in the case of ordinary superphosphate.

Retrogradation of soluble phosphoric acid when stored does not occur.

The raw phosphate need not be reduced to a finely powdered state.

Bicalcic phosphate can be employed as a fertilizer on all kinds of soil, even on sandy and boggy land.

Bicalcic phosphate will be of excellent use in the manufacture of "complete fertilizers."

Sacks are in no wise damaged by the product.

The product is a finely divided white powder, which is easily spread on the fields.

The process is now being carried out in a first small factory belonging to the Difosfat Company, at Trollhattan, Sweden.

Nitrogen and Carbides.—The action of nitrogen on strontium carbide is discussed in a paper by **S. A. Tucker** and **Y. T. Yang,** of Columbia University.

The action of nitrogen on calcium carbide is well known from the commercial cyanamide process. The action of nitrogen on lithium carbide has already been investigated and the present work with strontium carbide was taken up in the same manner, and included the following:

(1) Preparation of strontium carbide and analysis of the product.

(2) Absorption of nitrogen by the carbide and the influence of time, temperature and pressure.

(3) Analysis of the product and conclusions.

The results show that nitrogen is only absorbed by strontium carbide at fairly high temperatures. Nitrogen under pressure is evidently without advantage for its absorption by this carbide. Some of the nitrogen is fixed by this carbide as cyanide which is quite different from the product obtained by the absorption of nitrogen by the carbides of calcium and lithium, in which case the main product is cyanimid with only a trace of cyanide.

To sum up the results, strontium carbide absorbs nitrogen at atmospheric pressure when heated to a temperature of from 1000 deg. to 1200 deg. C. and the product so formed contains an appreciable proportion of cyanide.

* * *

The following papers were read by title only, since the authors were absent. The discussion was deferred to some later session when the authors would be present.

Simplifying Calculations by the Proper Choice of Units.—A paper on this subject by **Carl Hering** of Philadelphia, Pa., calls attention to the large number of unnecessary numerical calculations now required due to the numerous incommensurate conversion factors which must now be used in calculations in practice because the units at present used bear no simple relations with each other. This is especially the case in calculations involving energy in its different physical forms as, for instance, in electric furnaces in which chemical and physical processes are produced by energy which is at times chemical, physical, thermal, electrical, mechanical, radiant and luminous; it is always the same energy and yet is expressed in different units, therefore requiring repeated reductions.

It shows how the calculations involved could be greatly simplified by a proper choice of units. The general remedy proposed and urged is to use but one unit for each physical quantity, to make this unit some decimal multiple of the corresponding c. g. s. unit and to select this multiple so as to make the more usual relations of this unit to others a unity or a multiple of 10. Practically all of the troublesome conversion factors then disappear by becoming unity. All the electrical units were thus established. This simplicity is at present enjoyed by the physicist in the c. g. s. system and it could be equally well enjoyed in calculations in practice. The already existing practical units of this simple system should be retained. All forms of energy without exception are then stated in watt-hours or kilowatt-hours, and all forms of power in watts or kilowatts which are general units and not specifically electrical. This eliminates the heat units and such conversion factors as the mechanical equivalent of heat or electricity. The new system is simple, easy to understand and use, may be used in part or in conjunction with the older systems and does not necessarily imply a complete abandonment of the older units. It affords a uniform, international basis to which all physical data can be reduced and in which it can be compared. A table of conversion factors is added for reducing the more important of the older units to those of this simplified system.

POWER.

General:

1 watt = 10,000,000 ergs per second.

1 kilowatt = 1000 watts.

Mechanical:

1 gram-centimeter per second = 0.000,098,059,7 watt.

1 foot-pound per second = 1.355,73 watts.

1 kilogram-meter per second = 9.805,97 watts.

1 megadyne-meter per second = 10 watts.

I kilowatt = 100 megadyne-meters per second.

1 metric horse-power = 0.735,448 kilowatt.

1 horse-power = 0.745,650 kilowatt.

1 (feet fall × cubic feet of water per second) = 0.084,635,7 kilowatt.

1 (meters fall × cubic meters of water per second) = 9.805,97 kilowatts.

Thermal, chemical, physical, etc.:

1 gram-calorie per second = 4.186,17 watts.

1 thermal unit (B.T.U.) per minute = 17.581,6 watts.

1 pound centigrade heat unit per minute = 31.646,9 watts.

1 kilogram calorie per minute = 69.769,5 watts.

ENERGY

General:

1 erg = 1 dyne-centimeter.

1 watt-second = 10,000,000 ergs or dyne-centimeters.

1 watt-hour = energy of 10,000,000 ergs per second during one hour

1 kilowatt-hour = 1000 watt-hours.

Mechanical:

1 gram-centimeter = 980.596,6 ergs.

1 foot-pound = 0.000,370,501 watt-hour.

1 kilogram-meter = 0.002,723,88 watt-hour.

1 megadyne-meter = 10 watt-seconds.

1 (feet fall × cubic feet of water) = 0.023,509,9 watt-hour.

1 (meter fall × cubic meters of water) = 2.723,88 watt-hours.

1 metric horse-power-hour = 735.447 watt-hours.

1 horse-power-hour = 745,650 watt-hours.

Thermal, chemical, physical, etc.:

1 gram calorie = 4.186,17 watt-seconds, or 0.001,162,82 watt-hour.

1 thermal unit (B.t.u.) = 0.293,027 watt-hour.

1 pound-centigrade heat unit = 0.527.448 watt-hour.

1 kilogram calorie = 1.162,82 watt-hours.

FORCE.

1 dyne = 1.019,79 milligrams.

1 megadyne = 1,000,000 dynes.

1 megadyne = 2.248,25 pounds.

1 megadyne = 1.019,79 kilograms.

1 gram = 980.597 dynes.

1 pound = 0.44,4791 megadyne.

1 kilogram = 0.980,597 megadyne.

1 cubic foot of water (downward force) = 27.7676 megadynes.

1 cubic meter of water (downward force) = 980.597 megadynes.

PRESSURE.

1 barie = 1 dyne per square centimeter.

1 megadyne per square centimeter = 1 megabarie.

1 megabarie = 1,000,000 baries.

1 gram per square centimeter = 980.597 dynes per square centimeter.

JAMES F. KEMP, PRESIDENT AMERICAN INSTITUTE OF MINING ENGINEERS.

1 millimeter of mercury column = 1,333.21 dynes per square centimeter.

1 foot of water column = 0.029,888,6 megadyne per square centimeter.

1 inch of mercury column = 0.033,863,7 megadyne per square centimeter.

1 pound per square inch = 0.068,942,5 megadyne per square centimeter.

1 meter of water column = 0.098,059,7 megadyne per square centimeter.

1 kilogram per square centimeter = 0.980,597 megadyne per square centimeter.

1 atmosphere (760 mm.) = 1.013,24 megadynes per square centimeter (megabaries).

THERMAL RESISTANCE.

Thermal ohms = centigrade degrees ÷ watts = degrees per watt.

1 thermal ohm = a resistance requiring 1° C. per watt of heat flow.

1 thermal ohm = 0.000,000,1 c. g. s. unit of thermal resistance.

1 gram calorie unit = a resistance requiring 1° C. per flow of a gram calorie per second.

1 gram calorie unit = 0.238,882 thermal ohm.

1 c. g. s. unit = a resistance requiring 1° C. per flow of an erg per second.

1 c. g. s. unit = 10,000,000 thermal ohms.

Thermal resistivity:

1 gram calorie, cm. cb. unit = 0.238,882 thermal ohm, cm. cb. unit.

1 gram calorie, inch cb. unit = 0.606,762 thermal ohm, cm. cb. unit.

1 thermal ohm, inch cb. unit = 2.540,01 thermal ohm, cm. cb. units.

To reduce thermal conductivities given in B.t.u. per hour, per square foot, per inch thickness, per Fahrenheit degree, to thermal ohm, cm. cb. units, multiply the reciprocal of that number by 693.455.

Base Metal Thermocouples.—A paper by **O. L. Kowalke,** of the University of Wisconsin, gave an account of some observations on base metal thermocouples.

The object of this investigation was to determine the variations in the electromotive forces of the following well-known base metal couples when heated over different lengths and also after several heat treatments:

Nickel-chromium versus nickel-iron.

Nickel-iron versus nickel containing a little iron.

Nickel-steel versus nickel containing a little aluminum.

Nickel versus nickel-steel.

Nickel-copper versus iron-manganese.

The couples were all new and were cut to lengths of about 18 in. They were all compared one at a time against a standardized platinum couple in an electrically heated tube furnace. Five series of tests were made:

All couples were calibrated with lengths of 4 in. heated, and with lengths of 15 in. heated.

All couples were heated for 20 hours at 400 deg. C. and then calibrated with 15 in. heated.

All couples were heated for 24 hours at 600 deg. C. and then calibrated with 15 in. heated.

All couples were heated for 24 hours at 800 deg. C. and then calibrated with 15 in. heated.

The tabulated results show that the first two and last two couples do not indicate an error greater than 25 deg. C. at 1000 deg. C. when heated over 4 in. and 15 in. respectively. The first couple, however (nickel-chromium versus nickel-iron), undergoes a marked change after being heated at 800 deg. C. and gives indications resulting in differences of over 100 deg. C. at 35 millivolts. The couple nickel-steel versus nickel containing a little aluminum has a decided point of inflection which would introduce difficulties in arranging a scale for the indicating instrument.

Most of the couples are accurate to within 25 deg. C. when immersed at different depths and after heating for extended periods of time, but some may introduce errors approximating 125 deg. C. Caution should be used in purchasing and using these types of couples, and frequent calibrations should be made on accurate work.

Synthesis of Hydrocarbons.—The synthesis of hydrocarbons at high temperatures and pressures was the subject of a paper by **J. N. Pring** and **D. M. Fairlie,** of Manchester, England. The investigation, which was carried out at temperatures and pressures which were carefully measured and controlled, was directed mainly to the determination of the quantities of methane which are in equilibrium with carbon and hydrogen at different temperatures.

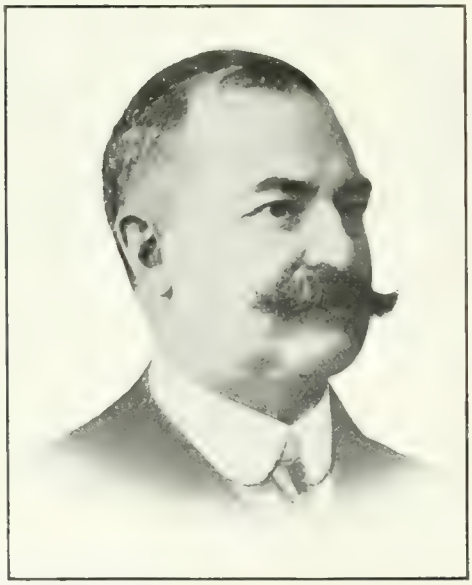
In this way it has been possible to obtain data which will correlate the values for the specific heats of hydrogen, methane, and different forms of carbon at high temperatures. The influence of temperature on the displacement of the equilibrium constant of a chemical reaction is a function of the heat change which accompanies the reaction at that particular temperature, while the heat of reaction itself changes with the temperature according to the specific heats of the substances taking part in the equilibrium.

The reactions which have been investigated in this work, viz. the synthesis of hydrocarbons, involve a case of the interaction of a solid with a gas. In the case of each hydrocarbon a certain equilibrium stage is reached when the particular hydrocarbon bears a definite ratio to the quantity of hydrogen present. The quantity of carbon does not come into consideration in this equilibrium, since its active mass does not vary under different conditions.

As methane is an exothermic compound, it follows that the equilibrium amount decreases with increase of temperature. Below 1000 deg., carbon and hydrogen at atmospheric pressure unite so slowly, even when the former is in presence of a catalyst like platinum, that equilibrium in the yield of methane cannot be reached in any reasonable time.

The velocity is considerably increased at high pressures, but even in this case it was not found practicable to determine the equilibrium value with methane below about 1100 deg.

Above this temperature, this synthesis was measured by heating carbon in the form of a rod in presence of hydrogen. The



DUISBERG, PRESIDENT VEREIN DEUTSCHER CHEMIKER

heating was effected by the passage of an electric current through the rod, which was thus the only part of the apparatus to be heated. The containing walls of the steel vessel were cooled by water.

Since methane is stable in larger amounts the lower the temperature, it follows that the quantity of this hydrocarbon finally yielded will correspond to the equilibrium at the temperature of the heated carbon, since no decomposition could occur in passing to the colder regions of the apparatus. A large amount of work has been carried out by the present authors on the synthesis of hydrocarbons at atmospheric pressure and it has been found that traces of ethylene are also formed at 1300 deg. and above, but the quantity does not reach any considerable magnitude below 1500 deg. (at 1400 deg. the quantity in equilibrium at atmospheric pressure is about 0.005 per cent).

The ethylene will react rapidly with the hydrogen in the cooler parts of the vessel, giving methane and thus gradually raising the quantity of the latter above the equilibrium value at the high temperature. However in the short time necessary to produce equilibrium with methane in these experiments at high pressure it was calculated that this disturbance would not reach any appreciable magnitude when working below 1500 deg.

With regard to the synthesis of acetylene, it was found in the earlier work that this first becomes noticeable (about 0.001 per cent) at 1650 deg., and the amount produced increases with the temperature, in accordance with the fact of its being an endothermic compound.

However, it has not been possible to determine the precise equilibrium values with acetylene, on account of the non-uniform temperature of the interior of the reaction vessel, which causes decomposition of the gas produced at the high temperature of the carbon to take place in regions of lower temperature. Moreover at temperatures where the quantity of acetylene attains any considerable magnitude an exact estimation of the methane equilibrium is no longer possible, on account of the rapid polymerisation of the acetylene with hydrogen, giving methane in the cooler parts of the vessel. For this reason, it has only been found possible in this work to measure with any accuracy the equilibrium with methane, and that only in the range of temperature between 1100 deg. and 1600 deg., though the experiments were extended up to 2100 deg. It has been shown moreover that in this range, and at pressures up to 200 atms, no hydrocarbons other than methane, ethylene, and acetylene can be formed or can exist in any detectable quantity.

Considering the synthesis of methane, since the equilibrium is expressed by the equation $C+2H_2=CH_4$ it follows in accordance with the law of mass action that $\frac{p.\ CH_4}{p.\ (H_2)^2}=K$ or the concentration of methane divided by the square of that of the hydrogen is a constant of any particular temperature. It follows from this that an increase in the pressure of n times will increase the ratio of methane to hydrogen n times.

A proof that definite equilibrium values are obtained lies in the fact of the same final quantity of methane resulting in whichever direction the reaction is made to proceed, and further by the same value being obtained for K, the equilibrium constant, whatever gaseous pressures were employed.

The author gives details of the apparatus employed of the preparation of the metals, analysis of gases, change of pressure and results.

Control of Small Electric Furnaces.—A paper by **Charles Burton Thwing,** of Philadelphia, Pa., describes a device for maintaining any desired temperature in small electric furnaces.

The plan was devised for use with a 10-kilowatt carbon plate resistance furnace, for which direct current only was available.

It is usual to employ alternating current for such furnaces, reducing the voltage as the resistance of the furnace falls with the rising temperature.

Where direct current is used, the control is usually effected by means of a rheostat, which, of course, wastes a considerable portion of the energy. The present plan dispenses with the use of a rheostat, by automatically opening the circuit once a minute and closing it after an interval regulated at will.

The control is effected by means of a small motor, which drives, by small gears, a cylindrical cam (C) 250 mm. (9.87 in.) long and 50 mm. (1.97 in.) in diameter, the cylinder being cut away on a taper from 350 deg. at one end to 0 deg. at the other. The pawl (P) is carried on a screw (s), which can be

turned by the handle (H) to set the pawl quickly and accurately to any desired position. When the pawl is resting upon the cam, the control switch (S) is closed. This automatically closes the clapper switch carrying the current; when the pawl drops, the control switch (S ft.) is closed, opening the clapper switch and cutting off the supply of energy from the furnace.

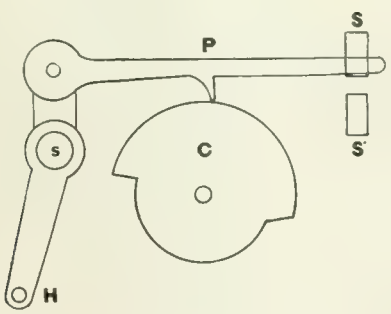
It is evident that the fractional amount of time during which the current is supplied to the furnace varies with the position of the pawl on the cam. While heating the furnace, the automatic switch is at rest; when the desired temperature has

MORRIS LOEB, PRESIDENT CHEMISTS' CLUB.

been attained, the motor which actuates the switch is started and the cam set to the position which has been found by trial to furnish the energy required to balance the losses by radiation.

The pawl may be set with great ease to within 1 mm. (0.03937 in), which is, of course, a finer adjustment than is required.

The control of the furnace is further effected by placing in series with the carbon resistance an auxiliary resistance of 0.2 ohm of nichrome tape, which increases to 0.3 ohm at the



ELECTRIC FURNACE CONTROL.

maximum temperature. The furnace is operated at 1300 deg. C. (2372 deg. Fahr.), and since this is too high for the nichrome to withstand permanently, the latter is placed in the base of the furnace, where the temperature does not exceed 1100 deg. C. (2012 deg. Fahr.). The increase of resistance of the nichrome with the rise of temperature tends to offset, in some measure, the diminishing resistance of the carbons, and so to prevent any accidental overheating of the furnace in case of failure of the operator to look after the adjustment of the controlling device.

The chief advantage of this plan over the rheostat is in the saving of energy. All the energy consumed is delivered to the furnace, except the small amount (about 50 watts) required to run the motor, and the much smaller quantity required to actuate the switch.

Reduction of Iron Ores in the Electric Furnace.

A paper by **D. A. Lyon,** of Pittsburgh, Pa., brings out the following points: The electric reduction furnace was not evolved with the expectation of competing with the blast furnace, but for the purpose of developing a furnace and a process which could be utilized in those localities where blast-furnace practice, due to the high cost of blast-furnace fuel, is not feasible.

That the following furnaces are now in successful operation:

Trollhättan, Sweden, 1 furnace	2500 hp
Domnarfvet, Sweden, 1 furnace	3500 hp
Hagfors, Sweden, 2 furnaces, at 3000 hp	6000 hp
Hardanger, Norway, 1 furnace	3500 hp
Heroult, Shasta Co., Cal., 1 furnace	2000 hp

While the following are nearing completion:

Hardanger, Norway, 1 furnace (extension)	3500 hp
Arendal, Norway, 3 furnaces, at 3000 hp	9000 hp
Switzerland, 1 furnace	2500 hp
Total furnaces built and building	32,500 hp

The Noble Electric Steel Company at Heroult, Shasta County, California, are also installing additional furnaces of sufficient capacity to give an output of 100 tons of pig iron a day.

The difference between the electric furnace and the blast furnace in operation is that in the electric furnace the electric current is used to replace that portion of the fuel in the blast furnace which is necessary for the melting down of the iron and the slag, and such being the case only one-third or less of the coke that is used in blast-furnace work is needed for the reduction of the iron oxides.

The main difficulties encountered in the development of the electric reduction furnace were maintenance of crucible walls and roof, and breakage of electrodes.

The problems yet to be solved are those which have to do with the volume of the shaft as compared with the size of the crucible; the reduction in the shaft; gas circulation; the preheating of the ore; the smelting of fine ores; the size of the unit; the efficiency of the furnace, etc.

As to comparative costs; for example, with coke at $6 a ton and with electric power at $16 per kw year, the reducing and melting costs of pig iron produced would be $6 in the blast furnace and $6.52 in the electric furnace, but if we take into consideration the initial cost of the blast-furnace plant, the efficiency of the electric furnace, etc., pig iron can probably be produced as cheaply in the electric furnace as in the blast furnace with coke costing $6 a ton and electric energy costing $16 a kw-year.

The commercial operation of an electric reduction furnace depends upon the development of cheap electric power, and although power can now be developed very cheaply by means of gas engines, etc., yet according to Kenesche it does not seem possible at the present time to develop it by means of gas engines at a low enough cost to permit of its use for iron-reduction furnace work. The lowest cost estimated by Kenesche is $22.50, and this takes into consideration the use of a by-product plant, the sale of the by-products, and the utilization of the waste gases from the electric furnace.

For the convenience of arrangement of the reports in this Congress issue the reports of the Section on Electrochemistry and of the Section on Mining and Metallurgy are grouped together, especially as there were a number of joint sessions of these two sections which should prove of particular interest to our readers.

Friday Session of Section on Mining and Metallurgy

The opening meeting of Section IIIa, devoted to Metallurgy and Mining, was held Friday, Sept. 6, at 10 o'clock, in joint session with the American Institute of Mining Engineers. The majority of papers presented were by members of the Institute, and may be accepted later for publication by the congress. The meeting was presided

W. F. HILLEBRAND, PRESIDENT SECTION ON ANALYTICAL CHEMISTRY.

over by Prof. J. W. Richards, president of the Section, assisted by Dr. J. B. F. Herreshoff, vice-president. The attendance was 45.

Some Metallographic Notes was the title of the first paper, presented by **Wm. B. Campbell,** the author, who discussed three types of antifriction alloys: lead-tin-antimony, copper-tin-antimony, and those with a zinc base. The speaker illustrated his remarks by lantern slides showing ternary diagrams of these alloys, and microphotographs representing conditions in the various areas of the diagrams.

The following papers were then presented by title only, the authors or representatives not being present:

The Carbon Iron Diagram. By **Henry M. Howe.**

Some Physical Characteristics of High-speed Tool Steel. By **J. A. Matthews.**

The Influence of Titanium on the Strength of Iron Castings was read in abstract by the author, **Bradley Stoughton.** The results of many experimenters were reviewed, showing the improvement in the physical qualities of iron by the addition of small quantities of titanium. Only 0.9 lb. of titanium per ton of steel is required to give increased resistance to wear. The author reached three conclusions: (1) that rails, car wheels, etc., are improved by the presence of titanium; (2) that this improvement is due rather to the cleansing effect of titanium on the steel rather than to the formation of an alloy with it; and (3) that the treatment must be very carefully carried out if the good results are to be obtained. The paper was briefly discussed by Dr. Richard Amberg and Prof. J. W. Richards.

In the absence of the authors or representatives the following papers were announced by title:

The Case-Hardening of Special Steels. By **Albert Sauveur** and **G. A. Reinhardt.**

Blowing In of Blast Furnaces. By **Albert Sweetser.**

Further Experience with the Gayley Dry Blast. By **E. B. Cook.**

Recent Tendencies and Developments in Open-Hearth Practice.—A paper by **Mr. R. B. Carnahan, Jr.,** of Middletown, Ohio, in which the author reports on the progress made in open-hearth practice in the United States, especially in the last three years.

He states that the improvements consist largely of metallurgical and chemical refinements, and that but little attention has been devoted to the mechanical side of the question.

He summarizes the developments under three heads: (a) improvements in open-hearth rails, (b) developments in special alloy steels, and (c) the making of pure iron.

The paper further states that the conservation movement that has been sweeping over the country has modified the viewpoint of the American manufacturer, and that in a comparatively short time the United States will be as progressive as Europe in research and development work.

A Novelty in Open-Hearth Practice, a paper by **N. S. MacCollum,** was read in abstract by a representative of the author, describing means devised to increase the capacity of open hearth furnaces. While it is comparatively easy to make a large amount of steel at one time, there is difficulty in handling it on account of the limited capacity of cranes and the difficulty in rapid and uniform casting. The author has overcome these difficulties by devising a bifurcated spout from the furnace to two ladles. The flow of steel from the furnace can be regulated and diverted to either ladle.

The following papers were then presented by title, in the absence of the authors:

Improvements on Kilns for Briquetting Iron Ores. By **A. Raman.**

The Present Status of Briquetting Iron Ores. By **A. Weiskopf.**

Effect of Iron Ore Briquettes on the Commercial Operation of Blast Furnaces. By **A. Weiskopf.**

The Manufacture of Coke. By **F. E. Lucas, W. H. Blauvelt, C. W. Andrews** and **J. De Forrest.**

Iron Coke. By **A. Lidoff.**

At the afternoon session, which was a continuation of the joint meeting with the American Institute of Mining Engineers, the first paper was on the **Micrography of Special Steel Castings,** and was read in French by the author, **R. Adan.**

Notes on Bag Filtration Plants

The use of the bag house for fume filtration was originally applied to the recovery of zinc oxide, but about twenty-five years ago it was extended to lead smelting. This paper by **Mr. Anton Eilers,** of New York City, formerly director and technical member of the executive committee of the American Smelting & Refining Company, and deals with the bag house in relation to the recovery of lead fume from blast furnace and converter operations.

AVERAGE TEMPERATURE OF GASES ENTERING FAN

	1909	1910	1911

November	103.02	89.15	90 7
December	94.6	87.0	81 9
Average	98.52	105.82	98.75

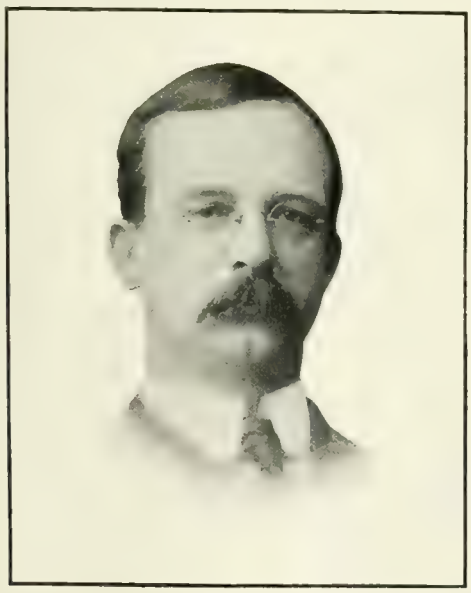
The first large bag house used in connection with lead smelting was built about 1887 at the Globe Smelting Refining Company's plant in Denver, Colo. When first installed it was not successful because the furnaces were run with hotter tops than is the custom at present. Following this first attempt the author made a good many experiments to determine the temperature of the gas and the quantity of sulphuric acid which it contained and as a result of this work the length of the flues in all smelting works was greatly increased and there was no difficulty in treating the gases in bag houses. It was found that in flues of a length of from 1000 to 1800 ft. there was no difficulty in accomplishing the end sought.

The author discusses the application of the baghouse in two different Western plants. One of these treats original ores as they come from the mines, the smelting charge containing an average of 10 to 12 per cent lead. The other smelter refines leady copper mattes and also operates a blast furnace treating refinery residues and ores.

Murray Plant Bag House.—The first of the two plants mentioned is situated at Murray near Salt Lake City, Utah. The outside dimensions of the bag house are 216 ft. 6 in. by 90 ft. 6 in.; height to roof trusses being 51 ft. 6 in. The total cost for construction was $127,194 including the cost of 4032 cotton bags, distributing flue, fans, motor, fan house, etc.

The original roof construction had to be modified on account of the tendency of the gases to attack the nails. After two years' service the nails holding the 1-in. board sheeting were eaten to such an extent that a heavy wind blew about one-third of the roof off from one partition. It was evident that nails could not be depended upon for holding the roof down and a new roof was put on top of the old one allowing an air space between the two. The construction of the old and new roof is shown in Fig. 1.

The bag house is completely divided into four compartments by means of brick partitions running from floor to roof; and each compartment is further divided below the thimble floor into four chambers. A distributing flue 16 ft. by 16 ft. runs



CHAS. L. PARSONS, PRESIDENT SECTION ON INORGANIC CHEMISTRY.

the entire length of the bag house and connects with each of the sixteen cellars by means of 42-in. bulls-eye valves. On the top of the distributing flue is a smaller one which is used to conduct the gases from any of the chambers that are in process of sintering, and return them to the main flue.

Each compartment has a steel stack to conduct the gases to the atmosphere. When the stacks were built the joints were lapped to in such a manner that condensed moisture finds its way to the outside of the stack corroding the metal and giving the stacks an unsightly appearance. Considerable moisture also trickles down inside the stack and originally gave considerable trouble by rotting the bags. To overcome this a lead-lined pan is used under the stack and a lead gutter conducts the accumulated moisture out on to the roof.

The bags were originally shaken by hand but in 1910 a new construction was adopted and each row of bags was hung on a

FIG. 1.—ROOF CONSTRUCTION OF BAGHOUSE, MURRAY, UTAH.

1½-in. gas pipe suspended by a U-bolt from the old bag hooks. By means of a lever on the outside of the building this gas pipe can be given a horizontal motion of about 5 in. which effectually removes the dust from the bags. By this device forty-two bags are shaken at one time. The arrangement of the bags and the manner of suspending them is shown in Fig. 2.

Cotton bags were originally used and cost $2.136 apiece, f.o.b. Murray. At the end of two years it was computed that the average life of cotton bags was seventeen months, eleven days. Had it not been for the adverse experience in roof construction and in the condensation of moisture in the stacks, the life of the cotton bags probably would have been longer. One

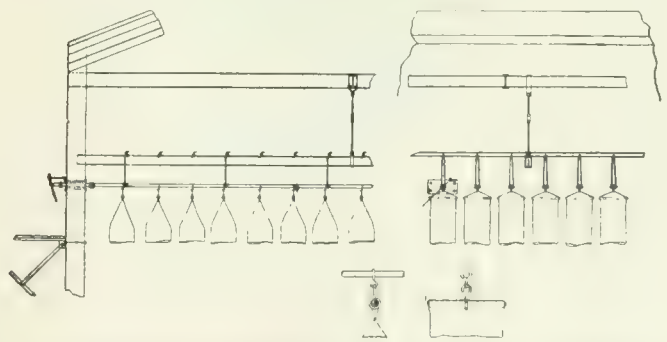

FIG. 2.—SHOWING ARRANGEMENT AND MANNER OF SUSPENDING AND SHAKING BAGS.

compartment was equipped with woolen bags costing $4.7185 apiece f.o.b. Murray. These were put into use May 19, 1909, and no bags have been replaced to date. As a result of the superiority of woolen bags over cotton the use of the latter has been entirely discontinued.

Filtering surface is provided at the rate of 3.45 sq. ft. per cubic foot of the gas per minute. When one compartment is closed this rate is reduced to 2.59 sq. ft. per cubic foot of

gas per minute and as one compartment is usually closed most of the time 25 sq. ft. was the basis used for calculating the number of bags needed.

All laborers connected with the bag house are required to take a shower bath and change clothes before leaving the bath house. Formerly rubber suits and helmets were furnished to the bag-shaker and foreman but later it was found that these were not essential to the men and that the main secret of good health was cleanliness, particularly avoiding eating their lunches with dirty hands and faces.

ing Company which is equipped with a plant for that purpose and works up fumes from a number of lead smelting plants. It is not good financial policy to provide every plant with an arsenic establishment, for it would be idle three-quarters of the time.

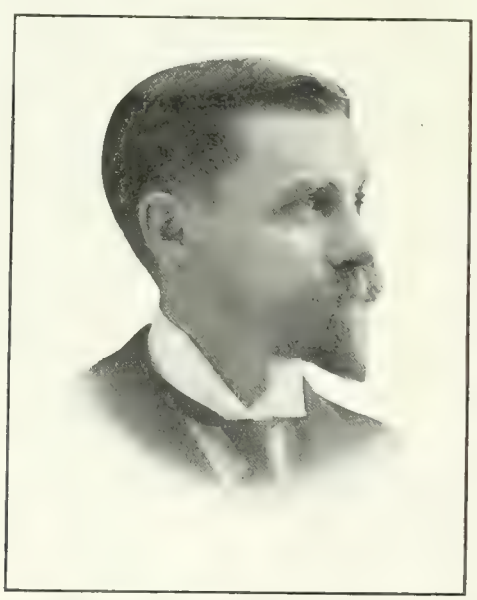
But if the Murray plant had happened to be the one provided with its own arsenic establishment, the cost of working up the fumes would not have been over $5.00 per ton, thus diminishing the loss shown above by $34,654.00, leaving the loss for four years and eight months still $24,101.28.

Recovery of bag-house dust for entire operation of Murray Plant Bag House [illegible]

	Charge Smelted	Fume recovered	Assay per ton Fume recovered	Per cent Charge Contents smelted	Value of Metals recovered
Weight	1,666,857 tons	13,857,645 lbs.		0.415%	
Gold	256,874.986 oz.	125.595 oz.	0.018 oz. p. ton	.049	$2,587.10
Silver	24,725,274.19 oz.	14,885.62 oz.	2.15 oz. p. ton	.063	8,028.25
Lbs. Lead	354,693,161 lbs.	4,492,288 lbs.	32.4%	1.269	141,745.02
Lbs. Copper	16,521,715 lbs.	1,947 lbs.		.0118	330.15
Total					$152,690.52

Operating Expense		*Outcome*	
Labor	$16,440.05	Treatment charge 662,742 tons at $3	$69,290.00
Motive Power	13,542.10	Operating cost	76,853.43
Supplies & Repairs	46,871.28	Total cost	$146,143.43
Total	$76,853.43	Value of metals recovered	152,690.52
		Gain in Labor & Supplies	$6,547.09

The above shows the apparent gain from the installation of the bag house in four years and eight months. But the figure does not include interest on the original investment, nor a fair percentage of same for amortization.



DR. A. D. RICHARDS, PRESIDENT SECTION ON MINING AND METALLURGY.

If these two items were included, as they should be, we would have:

Gain in 4 years and 8 months	$6,547.09
6% interest on cost of $127,194.89 for 4 years and 8 months	$35,014.57
5% amortization for 4 years and 8 months	29,678.80 65,203.37
Net loss in 4 years and 8 months	$58,746.28

On account of the advisability of extracting the high percentage of As_2O_3 from the fumes, the Murray fume has to be shipped to another works of the American Smelting & Refin-

The above figures show that, taking the immediate financial outcome only, bag houses are not profitable in lead smelting works, which treat ores low in the precious metals and especially in lead. But there is another consideration to be taken into account, when smelting works are, like Murray, located in the midst of farms and villages. This is the elimination of constant lawsuits, which are bound to be of frequent occurrence, when As_2O_3 and the sulphates of lead and other metals are permitted to drop down into the fields. It must be decided therefore in the case of each smelting plant, whether it is not good businss to expend the money for a bag house and for operating the same, though an immediate profit is not apparent.

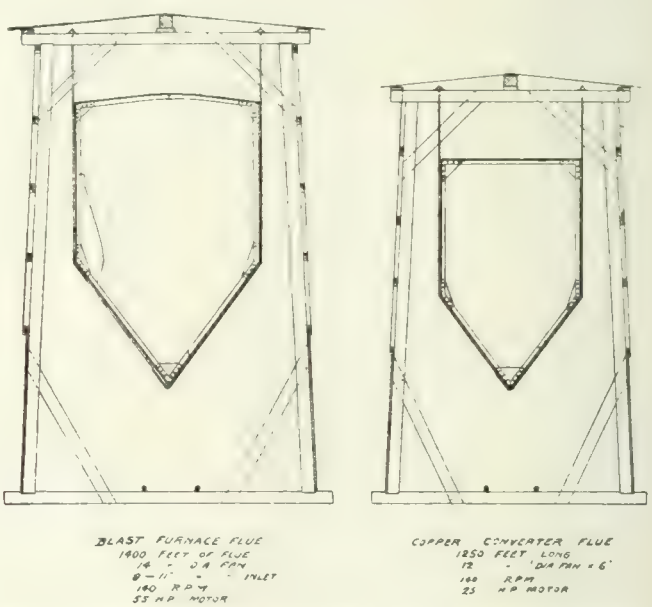


FIG. 3.—CROSS SECTION OF SUSPENDED BLAST FURNACE FLUE AND COPPER CONVERTER FLUE, OMAHA.

Converter Bag-House System at Omaha.—The Omaha plant of the American Smelting and Refining Company con-

verts a large quantity of leady copper matte. The gases from the converters are conducted through suspended flues, the cross section of which is shown in Fig. 3. The flues lead to a fan 12 ft. in diameter and 6 ft. wide, running at 140 r.p.m. and requiring 25 hp. The fan discharges into a bag house containing 940 bags, divided into two compartments. With the acid-lined converters one set of bags will filter 1600 tons of lead sulphate fume representing 4500 tons of blister copper. The secret of long life of the bags seems to be in the use of long flues, permitting rapid radiation, and a good vacuum above the bags so that the gases are removed rapidly. The average vacuum at the fan is about 0.8 of an inch of water and at the converter from 0.07 to 0.15 of an inch.

CHAS. E. MUNROE, PRESIDENT SECTION ON EXPLOSIVES.

The average temperature in the bag chamber is 140 deg. F., varying from 100 deg. to 180 deg. Bags are made of Osnaburg sheeting, with a loop at the closed end, through which passes a 1-in. pipe or stick to support the bag.

In the above table are some pertinent figures relating to the converter bag house operations at Omaha.

Blast Furnace Bag-House System at Omaha.—The blast-furnace charge runs high in lead, rather above 40 per cent than under. The recovered fume contains about 50 per cent lead, considerable carbon and arsenious acid. In sintering this fume, the arsenic is concentrated to about 20 per cent. Some experiments were made to see how far the arsenic could be eliminated from the fume by roasting. Several results show a reduction from 13.1 per cent As to 3.6 per cent As.

The burned fume is fused in a small reverberatory, allowed to cool in pots and then charged alone into the residue furnace of the lead refinery, reducing a little lead and removing silver. The antimonial and arsenical slag resulting from this operation is reduced in a blast furnace, producing an impure lead which is later refined by a special process of fusion.

In the discussion which followed, **Dr. F. Heberlein** stated that the bag system of fume collection had not been adopted in Europe because wet condensation had proved more satisfactory and appropriate to European conditions. Further the cost of plant for bag filtration was greater than for wet condensation. There was no difficulty in operating wet condensation of fume by sprays or churning devices, even at a temperature of 70° C. The addition of a little lime to the spray was helpful, and the efficiency of the plant usually averaged 92 per cent. recovery of the solid fume. An additional reason why wet condensation is preferred in Europe is on account of better sanitary conditions than can be obtained in bag houses.

Mr. Eilers, in replying to Dr. Heberlein stated that he had been given figures showing that the present construction of the bag house is less expensive than the wet condensation system, and that its operation is, perhaps, more economical.

The Development of the Reverberatory Furnace for Smelting Copper Ores.

A paper by **E. P. Mathewson,** of Anaconda, Mont., general manager for the Anaconda Copper Mining Company and the International Smelting & Refining Company. The author traces the development of the reverberatory furnace from early Welsh practice to modern American types. The principal change has been in the size and capacity of the furnace, as shown in the following data on the Washoe Smelting Works, at Anaconda, Mont.

The reverberatory furnaces as originally built at the Washoe smelter had a hearth area of 19 ft. in width by 50 ft. in length. After some months of operation it was decided that a longer

The features that distinguish the modern reverberatory are its length, solid bottom (monolith of quartz fused), structural steel conker plate for bridge-wall, frequent charging, infrequent skimming of slag, the large body of molten matte retained in the furnace to assist in melting and distributing the charge, no leveling of charge by means of rabble; thick roof (15 in. to 20 in. of silica brick); fettling only once a month in many plants, practically continuous operation; recovery of waste heat in the form of steel; and, where coal is used for fuel, the recovery of the unburnt coal from the ashes.

During the development of the reverberatory furnace to its present state of efficiency a great many schemes were tried out and abandoned; for example, the preheating of the air by passing it under the furnace bottom or around the walls of the flue or firebox, and forced blast under the grate.

A great variety of fuel has been used; at Kyshtem, producer gas from wood; at Cananea, Texas oil; at Humboldt, fuel oil from California; at McGill, Nev., fuel oil.

As showing the performance of the modern reverberation furnace, the following record from the Steptoe plant at McGill, Nev., is given:

Chemistry of the Reduction Processes in Use at Anaconda, Mont.

A paper by **Frederick Laist**, assistant superintendent of the Anaconda Copper Mining Company, Anaconda, Mont. The author first gives a complete list of all the minerals existing in the ore and rock received at the smelter, but states that the following minerals are responsible for, say, 95 per cent of the reactions in the various furnaces.

The discussion is confined to the reactions going on between these substances.

Chalcocite, Cu_2S,	Sphalerite, ZnS,
Covellite, CuS,	Haematite, Fe_2O_3,
Bornite, Cu_2FeS_3,	Iron oxide, FeO,
Enargite, Cu_3AsS_4,	Limestone, $CaCO_3$,
Pyrite, FeS_2,	Silica, SiO_2,
	Alumina, Al_2O_3.

The chemistry of the following departments of the reduction works is then considered, developing the various reactions which take place. These are summarized in the following tabulations:

Roasting Furnace Reactions

Charge consists of:

Gangue, FeS_2, Cu_2S, CuS, Cu_2FeS and Cu_3AsS_4.

(1) (a) $7FeS_2 = Fe_7S_8 + 6S$.

(1) (b) $6S + 12O = 6SO_2$.

(2) $FeS + 3O = FeO + SO_2$.

(3) $2FeO + O = Fe_2O_3$.

(4) $Cu_2S + 4O = 2CuO + SO_2$.

(5) $CuS + 3O = CuO + SO_2$.

(6) $Cu_2FeS_2 + 10O = 3CuO + FeO + 3SO_2$.

(7) $2Cu_3AsS_4 + 25O = 6CuO + As_2O_3 + 8SO_2$.

(8) $FeS + 4O = FeSO_4$.

(9) (a) $SO_2 + O$ (in presence of Fe_2O_3) $= SO_3$.

(9) (b) $SO_3 + FeO = FeSO_4$.

(10) (a) $FeSO_4 = FeO + SO_3$.

(10) (b) $CuO + SO_3 = CuSO_4$.

Reverberatory Furnace Reactions.

Charge consists of:

SiO_2, Al_2O_3, FeS, FeO, Fe_2O_3, Cu_2S, CuO, $CaCO_3$, $FeSO_4$, and $CuSO_4$.

(11) $CaCO_3 = CaO + CO_2$.

(12) $8FeO + CaO + 9SiO_2 = \underset{(CaO)}{(8FeO)}\,.9SiO_2$

(13) $4FeS + 6CuO = 4FeO + 3Cu_2S + SO_2$.

(14) $4FeS + 6CuSiO_3 = 4FeSiO_3 + 3Cu_2S + SO_2$.

(15) $3Fe_2O_3 + FeS = 7FeO + SO_2$.

(16) $CuSO_4 = CuO + SO_2 + O$.

(17) $FeSO_4 = CuO + SO_2 + O$.

Blast Furnace Reactions.

Charge consists of:

SiO_2, Al_2O_3, FeS_2, Cu_2S, $CaCO_3$ and C.

(18) $FeS + 3O = FeO + SO_2$.

(19) $C + 2O = CO_2$.

(20) $7FeO + 9CaO + 12SiO_2 = \underset{(9CaO)}{(7FeO)}\,.12SiO_2$.

(21) $2((FeO)_2.SiO_2) + SiO_2 = (FeO)_4.3SiO_2$.

Photo. by Gessford.

MARSTON T. BOGERT, PRESIDENT SECTION ON ORGANIC CHEMISTRY.

Converter Reactions.

Charge consists of:

Cu_2S, FeS and siliceous ore.

(22) (a) $FeS + 3O = FeO + SO_2$.

(22) (b) $2FeO + SiO_2 = (FeO)_2SiO_2$.

(23) $CuO + SiO_2 = CuSiO_3$.

(24) (a) $Cu_2S + 4O = 2CuO + SO_2$.

(24) (b) $Cu_2S + 2CuO = 4Cu + SO_2$.

The author also appends a diagram, Fig. 1, to show graphically the elimination of the valueless constituents of the ore.

Iron Coke.—A paper by **A. P. Lidoff,** of Charkov, Russia, in which the author describes a new material useful in the making of electrodes.

After studying the composition of dust from blast furnaces he has come to the conclusion that by repeatedly passing it through magnetic machines it is possible to obtain a product the greater part of which is ferric-oxide.

If we mix the product thus obtained with gas coal slack, capable of giving a good coke (in proportion of one part of dust to two or three parts of coal), coke thus mixed at a high temperature, under pressure, there is obtained a porous coke containing metallic iron regularly distributed through it.

The specific gravity of this coke and its strength and porosity are dependent on the quality of the coal and the composition of the dust.

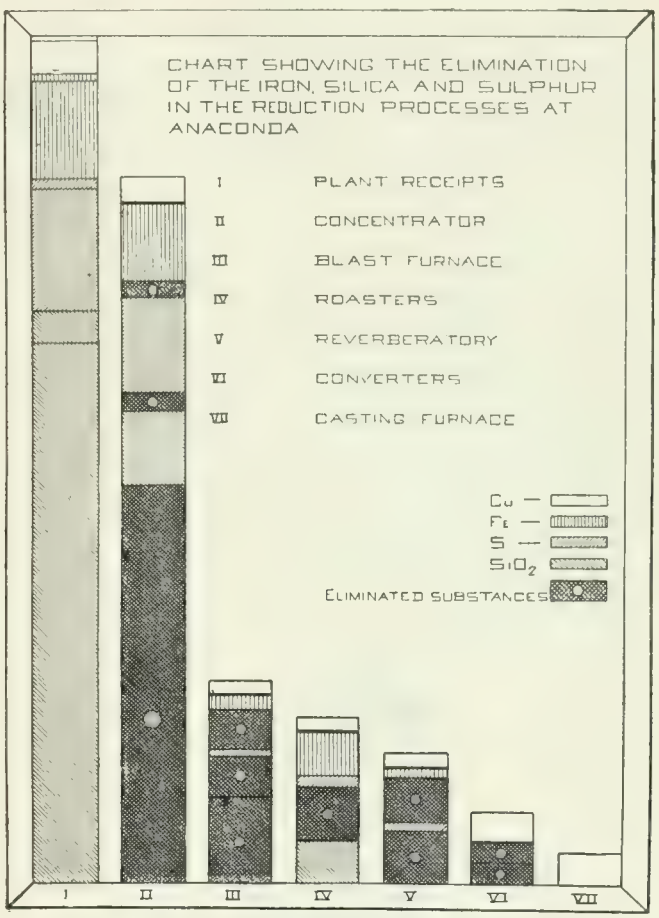

FIG. 1.—ELIMINATION OF IRON, SILICA AND SULPHUR

The Sulphatizing Roasting of Copper Ores and Concentrates.

A paper by **Utley Wedge,** of Ardmore, Pa., in which the author gives results of tests made on various copper ores to investigate the possibility of rendering the copper soluble by converting it to copper sulphate. The author is of the opinion that such a process would find application where suitable conditions for smelting are not available. By roasting the copper to sulphate and then leaching with water or dilute acid, or both, it is possible to produce either cement or electrolytic copper, or insoluble salts of copper which can later be reduced to metal. The Wedge mechanical roasting furnace is the device which the author believes to be well adapted to this process.

This paper presents facts relating to only one step in the wet process of copper extraction and deals only with the formation of sulphate of copper by roasting copper ores or concentrates.

One per cent of copper contents requires, theoretically, ½ per

cent of sulphur to form sulphate of copper. In practice, it is necessary to have present an excess of sulphur over this theoretical amount. If insufficient sulphur is present in the material to be treated, it is then necessary to add sulphur in some form, either as sulphur, SO_2, SO_3 or in the form of a sulphide or sulphate or sulphuric acid. Iron sulphides are very desirable in ores, when it is desired to sulphatize the copper values, and zinc, lime, lead and magnesia, if present in forms that will consume sulphur, are undesirable.

The principal reactions which enter into the sulphatizing of copper sulphides, are as follows:

CuS decomposes in roasting to $Cu_2S + S$ and the free atom of S burns to SO_2 at temperatures above 350 deg. C. (662 deg. F.). Cu_2S at furnace temperatures below 500 deg. C. (932 deg. F.), reacts principally as follows:

$$2\,Cu_2S + 5\,O_2 = 2\,CuO + 2\,CuSO_4.$$

At higher temperatures, the principal reaction is

$$Cu_2S + 2\,O_2 = 2\,CuO + SO_2.$$

Different copper sulphide minerals behave differently at furnace temperature, but the above formulas show the tendency common to all copper sulphides to form some quantity of copper oxide at all furnace temperatures.

In roasting to secure the highest per cent of water-soluble copper, the constant formation of the copper oxide is the chief obstacle to be overcome.

The presence of iron sulphide with copper sulphide in the roasting process assists in sulphatizing the copper oxide thus formed. At furnace temperatures below 600 deg. C. (1112 deg. F.) there is some basic sulphate of iron formed, which, at temperatures above 530 deg. C. (986 deg. F.), roasts to Fe_2O_3 and SO_3 and the SO_3 gas may combine with the CuO to form $CuSO_4$ which is practically stable at temperatures below 650 deg. C. (1202 deg. F.), or, the CuO may react directly with the $Fe_2(SO_4)_3$, according to the formula

$$3\,CuO + Fe_2(SO_4)_3 = Fe_2O_3 + 3\,CuSO_4.$$

Even the portion of iron sulphide which roasts to Fe_2O_3 is of some assistance in sulphatizing the CuO, as at temperatures

DR. A. MEIZ, PRESIDENT SECTION ON COAL TAR COLORS AND DYESTUFFS.

between 500 deg. C. and 750 deg. C. the iron oxide acts as an energetic catalyzing agent for the oxidizing of the SO_2 to SO_3, which in turn tends to combine with the CuO to form $CuSO_4$.

Also, SO_2 generated in the furnace, either from the copper or iron sulphides, tends to sulphatize the copper oxide.

The following tests are selected from many given by the author, to show the application of the process:

Analysis of Ore:

Cu	1.8 per cent
Fe	9.61 " "
S	10.37 " "
CaO	1.10 " "
MgO	0.72 " "
Insol	61.21 " "

Copper present as chalcopyrite; the gangue was diabase.

This ore was given a single treatment in a Wedge multiple hearth muffle furnace (Patent No. 654,335, July 24, 1900), having a diameter of 9 ft. 9 in. with five hearths, being the same furnace as was used in the previous test.

Actual leaching of this ore showed a recovery by

Water extraction	73.7 per cent of copper in ore
Weak sulphuric acid.....	15.7 per cent of copper in ore
Making a total of.....	89.4 per cent of the total copper in ore.

It is believed that this ore, sulphatized in a larger furnace of the Wedge type, would yield still better results.

Tests so far given were made with ores containing copper as chalcopyrite.

The following test was made with an ore in which the copper was present chiefly as Bornite with some silicate and carbonate of copper.

Analysis of Ore:

Cu	3.40 per cent
Fe	11.05 " "
S	13.02 " "
SiO_2	63.90 " "

This ore was ground to 20-mesh and was given a single treatment in a small furnace test and showed:

Water-soluble copper	80.80 per cent of total copper contents
Acid-soluble copper	11.8 per cent of total copper contents
Total recovery	92.6 per cent

The above results have since been duplicated with this ore in a Wedge mechanical muffle furnace 20 ft. 0 in. in diameter with five hearths and sufficient sulphuric acid is recovered from the SO_3 in gases leaving the furnace to recover the oxide of copper formed and make the extraction as above shown in the subsequent leaching operation.

It has been shown that copper ores containing little or no sulphur or iron can be treated by sulphatizing roasting by the addition of sulphide of iron, in the form of iron pyrites.

Analysis of Ore:

Cu	3.14 per cent
Fe	2.25 " "
S	none
Insol	85.5 " "

This ore contained copper as carbonate and the gangue was porphyry.

This ore was mixed with 5 per cent of iron pyrites containing 47.5 per cent sulphur.

The test was made in a 9 ft. 9 in. Wedge mechanical muffle furnace with five hearths and the analysis of the calcine allowed 92 per cent of the copper to be soluble in water. The copper solution was very pure, containing only from 0.1 per cent to 0.2 per cent Fe_2O_3 to 7 per cent copper sulphate. Copper precipitated from the solution with clean scrap iron tested 96 per cent pure cement copper.

The author concludes that the process may, in special cases, displace the smelting process.

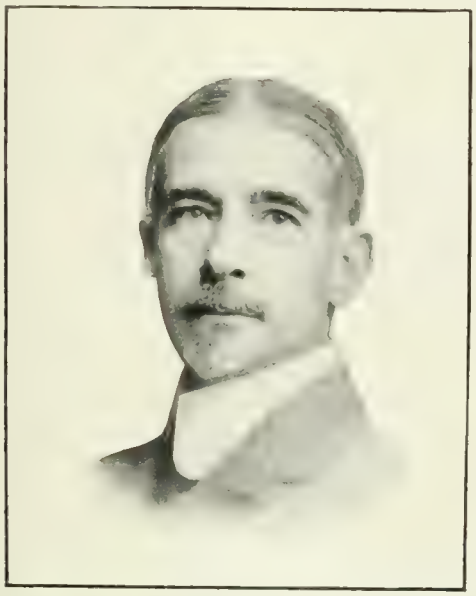
Manganese Bronze Tests.—On account of the increasing industrial importance of manganese bronze it has become necessary to know more about its physical properties and particularly the methods of testing the metal and establishing standard specifications. In a paper by **Wm. M. Corse** and **V. Skillman,** of the Lumen Bearing Company, Buffalo, N. Y., the authors lay stress on the importance of properly prepared test-coupons, for they show that such coupons do not uniformly represent the physical conditions of the casts of which they are a



W. D. HORNE, PRESIDENT OF SECTION OF INDUSTRY AND CHEMISTRY OF SUGAR.

part. The difficulty of getting a representative test coupon is greater in the case of metals of high shrinkage such as manganese bronze.

Test coupons in general may be roughly divided into three classes; first, sand-cast coupons of about the size of the test bar desired. Second, some modification of the first class having a riser to take care of the shrinkage; and third, chill-cast coupons.

The first class are not suitable for manganese bronze, but of the second class the authors have found some to be very satisfactory. The best pattern consists of a block 3 in. wide, 4 in. high and 4½ in. long, with 1-in. square cubes extending lengthwise over each side on the bottom and along the center of the bottom itself, making three test coupons in all. This pattern is not greatly influenced by differences in pouring temperature and is therefore better than a sand-cast coupon which rapidly decreases in strength and elongation with decrease in pouring temperature. Chill-cast coupons will give from 5 to 10 per cent greater tensile strength and slightly more elongation than the sand-cast coupon recommended above. Nevertheless, the points in favor of the use of the chill-cast coupon are well taken, and if the results are used with a full understanding of all the conditions, no hardship will be imposed on either the buyer or seller. More or less trouble will arise, however, when alloys are bought and tests made without a knowledge of the manner in which the test coupon is made.

The authors are of the opinion that the elastic limit and reduction of area tests are of little value and believe that the personal element enters into them too largely to make the results reliable. The use of a proper test coupon coupled with intelligent testing will materially assist in the progress of the alloy industry.

This paper was then read:—

The Evolution of the Modern Lead Blast Furnace. By F. Cazin.

The Dwight & Lloyd Process of Roasting and Sintering.—A paper by **Mr. Arthur S. Dwight,** of New York City, who has been closely identified with smelting processes and has given special attention to the preparation of furnace feed.

The Dwight & Lloyd process of sinter roasting was described by Prof. H. O. Hofman before the Seventh International Congress of Applied Chemistry, and has received so much notice in the technical press and in the proceedings of scientific societies, that no attempt is made in the present paper to describe either the principles or the procedure. The object of this paper is to describe briefly the progress that has been made in the past three years, and the results that have been achieved. The process of Dwight & Lloyd is an improvement on the older types of blast-roasting processes as typified in the methods of Huntington-Heberlein, Savelsberg and others. By means of this improvement the following broad results are obtained:

1. Instead of the huge cakes of pot-product, dense and slag-like, requiring much labor to handle and break up to the proper size for smelting, and accompanied by a considerable proportion of fines, a thin slab of crisp, cellular "biscuit" is produced which, while easy to break into pieces of the right size for smelting, is yet strong enough to withstand ordinary handling and to support the weight of the charge column in the blast furnace. When the operating conditions are intelligently adjusted, the amount of fines made in the Dwight & Lloyd product should be practically *nil*. Much of the success of the process has been due to the extraordinarily favorable properties of this peculiar and distinctly novel metallurgical product. The apparatus used for manufacturing this thin cake may be either *intermittent* or *continuous* in action, the latter being preferable for many important reasons which will be hereafter discussed.

2. By feeding the fine materials to be sintered in a thin layer of uniform thickness on the perforated bottom of a traveling conveyor, and after automatically igniting the charge on one surface, passing it through a section of the apparatus where air currents are caused to permeate the thin layer, the original ignition is propagated through the mass in such a way that it progresses from the surface of ignition to the opposite surface, and thereby effects a complete sintering of the mass from one surface to the other at the expense of the sulphur, carbon or other combustible element present which supplies the necessary fuel. The conveyor is meanwhile moved at such a speed that the agglomerated product is ready to automatically discharge as soon as the operation is complete.

Lead smelters generally have been very prompt to adopt the Dwight & Lloyd process and every plant which has been installed in the United States since 1909 has been in practically continuous operation up to the present time. These plants are variously treating lead, copper and iron ores, the majority being in lead works.

In copper metallurgy the advantages of sintering as a preliminary to smelting have not been as self-evident as in lead smeltings, but they are none the less a fact. The process is as perfectly applicable to copper ores as to lead ores with no essential change in plant or procedure. In fact, the process was originally worked out on copper ores. Four plants are now in regular operation on copper ores, two of which are at present increasing their capacity by adding more units. Most of the interest of the copper metallurgists has lately been directed toward the improvement of the large reverberatory. It is interesting to note in passing that on the basis of present smelting costs in certain large copper smelteries having both blast and reverberatory-furnaces, combined with average sintering costs elsewhere prevailing, *sintering plus blast-furnace smelting* already rivals in cheapness *mechanical roasting plus reverberatory smelting*, with large potential advantages remaining in favor of the blast furnace when treating this peculiarly favorable material.

The agglomerating of fine iron ores, pyrites cinder, flue dust,

etc., have been the most recent of the practical applications of this process, the only difference in procedure being that the internal combustion necessary for the sintering is derived from inter-mixed carbonaceous ingredients instead of sulphur.

Of the different types of apparatus designed by Dwight & Lloyd, the "straight line" machine has become standard. In Europe the "round table" type seems to be preferred, being used exclusively. None of the "drum" type machines are in use. Some of the intermittent down-draft pans have been given

LEO H. BAEKELAND, PRESIDENT OF SECTION ON INDIA RUBBER AND OTHER PLASTICS.

a practical trial in America and Australia in an experimental way as a preliminary to the adoption of continuous machines. The continuous system has always proved its superiority in the essentials, viz., lower operating cost per ton and better quality of product with less production of fine material. The net result is to make the efficiency of the continuous apparatus from 1½ to 3 times that of the intermittent, which efficiency factor duly affects all cost items both of investment and operation.

The reasons for the superiority of the continuous system must be apparent to any one familiar with the practical details of sintering. Success depends to a pre-eminent degree on the maintenance of absolutely uniform conditions of adjustment as to mixture, permeability, thickness of layer, size of material, compression, moisture, air blast and heat-treatment. With the intermittent plan, all these conditions have to be re-established for each small batch, thereby demanding a maximum of attendance, and even then the desirable conditions cannot be obtained with anything like the degree of perfection that is easily and automatically secured by the continuous mechanism.

Furthermore, in the intermittent process, it is difficult to judge when the layer is completely sintered, because it finishes on the under side next to the grate and, therefore, the finish is out of sight of the attendant. If discharged prematurely, an undue proportion of raw fines will result. The sintering time of the preceding charge cannot be taken as an accurate index, because the successive charges necessarily vary widely in degree of compression, and consequently in time of sintering. It is to be expected therefore that the attendant will allow ample time for the entire charge to finish which, of course, means some waste time, thus diminishing the possible output of the apparatus. On the continuous machine, a cross section of the finished cake is always visible at the point of discharge and the speed of travel of the machine can be instantly varied to meet the best requirements.

Labor and cost of operation are greatly reduced by the Dwight & Lloyd machines. Two men per shift can attend three machines. With a well-designed plant of one unit, treating about 100 tons per day, a sintering cost of 50 cents per dry ton of charge treated can be expected. This includes royalty and repairs. Labor will represent about half this cost.

The cost of plant will vary from $80 to $200 per ton-day capacity, depending on many local conditions. The average cost of plants installed up to date has been $150 per ton-day capacity. Various fuels are used for igniting the charge. Gasoline seems to be preferred on account of convenience. About ½ gal. of gasoline is used per ton of ore treated. Repair costs are low, the principal item being grate-bars. At some plants the cost for repairs, lubricants and other supplies has not exceeded an average of 5 cents per ton.

A notable effect of sinter roasting has been the increased capacity of blast furnaces treating the sinter. The product of the Dwight & Lloyd machine is especially desirable and constitutes a "pre-digested" furnace feed.

A recent application of the machines is in sulphuric acid manufacture. Gas tests show a range of SO_2 varying between 2 per cent and 7 per cent, and by taking a few precautions, the richness of the gas can be maintained at a suitable point for acid making. Another interesting possibility presents itself in the removal of sulphur in the metallic form. As the charge burns, some of the sulphur tends to retreat downward in advance of the zone of fire and liquate from the cake in the form of molten drops of sulphur.

Dr. F. Heberlein, the originator of the system of sinter roasting in pots, spoke briefly, confirming the claims of superiority of the Dwight & Lloyd process over the original Huntington-Heberlein idea. The former seems so simple that people may wonder why it was not thought of long ago, but such is not the development of inventions. Although the pot system has been greatly improved since its introduction, and capacity has been increased to 40 tons, the method is still deficient in making a suitable physical product and in the sanitary conditions which surround the operation.

The Decomposition of Metallic Sulphates at Elevated Temperatures. A paper by **H. O. Hofman** and **Mr. Wanjukoff,** presented in abstract by Mr. Hofman, giving method of determining the temperatures at which metallic sulphates begin to decompose, and at which the decomposition is complete. These reactions are of importance in connection with the roasting of metallic sulphides. In the work of former investigators, the pyrometric data do not always agree, and the authors undertook this work for the purpose of securing more accurate results.

Three methods have been used to determine the decomposition temperatures of sulphates: (1) heating in an evacuated tube measuring the changes in pressure at different temperatures; (2) heating in a closed tube in an electric furnace; and (3) heating in a current of air in an electric furnace. The first two methods are not applicable to commercial conditions, so the authors devised the last method in which the heat is applied first to the furnace containing an empty boat, and later to the furnace containing a boat filled with the material under test. By plotting the temperature curves for the two conditions and noting the points of deviation of the latter from the former, the decomposition points may be quite accurately determined.

Development of the American Water-Jacket Lead Blast-Furnace.—Lead smelting was first practiced at Eureka, Nevada, about 1870. From a crude beginning the industry has extended into Utah and Colorado and has been developed to a point of comparatively high efficiency. In a paper by Mr. **R. C. Canby,** of New York City, the growth and development of the water-jacket furnace is traced from the first draft furnace at Eureka, Nevada, in 1870 to the most modern Western lead smelter of 1910. The author divides his consideration of the subject into decades.

In the first decade 1870-80 furnaces were usually 2 or 3 ft. square and those that had blast were supplied by small fans or blowers. A round water-jacket furnace was also introduced at this time. Albert Arents introduced the siphon-tap and reestablished the furnace bosh. Otto H. Hahn also made his imprint on lead smelting at this period.

In the second decade—1880-90—a decided advance was made in furnace construction and in business management; works became centralized and the individual smelter at the mine disappeared. Furnaces were now constructed rectangular in shape, about 36 in. wide and 60 to 80 in. long. Cast-iron jackets were gradually improved and remained constant until the possibilities of cheaper manufacture made steel jackets more attractive.

In this decade also the necessity of saving matte became more apparent and led to the construction of the continuous-flow fore-hearth and the Devereaux pot, with a tap hole in the side. A system of centrifugal separation was also tried to separate matte and slag and while it proved a failure from a mechanical point of view it demonstrated that the silver in the slag was very largely mechanically disseminated as sulphide. The matte formed in this period was very largely iron matte, with little or no copper and caused high silver and lead losses. In the decade from 1890-1900 metallurgists began to realize the beneficial effect of a high matte fall and in the beginning of this period we find all lead furnaces with a matte fall of from 5 to 10 per cent of first matte ranging from 2 to 8 per cent copper and occasionally reaching 12 to 15 per cent.

The development of a high blast occurred about this time but it was found to result in still higher lead losses and finally was abandoned. In this decade also it became evident that many unsatisfactory conditions in the furnace were due to the fineness of the material and attention was directed to the production of sintered products which would be more suitable for the furnace.

In the fourth decade—from 1900-10—there was a movement toward increasing the size of the furnace, in the shape of a

Copyright, Harris & Ewing.

DAVID T. DAY, PRESIDENT OF SECTION ON FUELS AND ASPHALT.

wider rather than a longer furnace, but general practice still continued with a furnace of 36 in. width. The problem of handling larger tonnages became more apparent about this time and with it came the necessity of more perfect separation of the matte from the slag. Mechanical feeding was also developed but was not generally adopted.

From 1910 to the present time the greatest development in lead smelting has been in accessory processes rather than in the actual smelting itself. The sintering furnaces of Dwight-Lloyd have produced a material which has greatly increased the capacity of the blast furnaces and has correspondingly reduced labor and general costs as well as the percentage of fuel required.

More attention has been paid to metallurgical losses and gains; and whereas it was formerly customary to take account only of those metals for which payment was made to the

FIG. 1.—THE FIRST SUCCESSFUL DRAFT FURNACE AT EUREKA, NEVADA, 1870.

miner, it has now become general practice to charge the entire metal income to the plant. The author concludes that any further improvements in lead smelting will be more promptly achieved until possibly the entire system of treatment of lead ores will in no way resemble present practice.

The Development of the Parkes Process in the United States.

A paper by **Ernst F. Eurich,** New York City, describes the development of the Parkes process for desilvering lead bullion. Alexander Parkes patented the use of zinc for this purpose in 1851. The early efforts to use it in England were not successful nor was the attempted introduction into the United States, the latter being due to the fact that our Civil War was beginning about that time. In 1864 Edward Balbach, of Newark, N. J., patented a process based on similar principles and added the use of a black-lead retort for the purpose of distilling zinc from the alloy of silver and lead.

Briefly stated, the Parkes process consisted in adding to the silver-lead bullion from 1 to 2 per cent of zinc, cooling, skimming the alloy that rises to the surface, liquating it in an iron retort, distilling the rich alloy in fireclay retorts, thus regaining the zinc, and finally refining the desilvered lead in a cast-iron pan in a reverberatory furnace. The Balbach process first liquated the softened bullion and conducted the metal into a kettle which contained the proper quantity of melted zinc. This was finally stirred, cast into moulds and again liquated after which the lead was practically free from silver. The rich alloy was then distilled, the zinc being recovered in the condenser and the rich lead cupelled. As both processes became more widely adopted the Balbach process was modified to resemble the Parkes process more closely.

Most of the American works differed somewhat in details of operation, but there was one feature which was common in all,

namely, the terrace construction of the desilvering plant. The softening furnace occupied the highest level, the desilvering kettle next, the refining furnace below this, and lowest of all the moulds for the pig lead.

The author traces the development of the process by considering each operation separately. The first operation consists in softening the lead bullion, which consists in melting it in a wrought iron covered with firebrick laid in an inverted arch of 6 to 9 in. rise. This has become standard construction wherever the Parkes process is used. Various efforts were made to prevent the corroding action at the lead line by various water-cooling devices. These were finally abandoned with the advent of magnesite bricks.

The size and capacity of softening furnaces increased rapidly from 10 tons up to 90 tons, the latter being an economical limit when the furnaces were charged by hand. With mechanical handling the capacity of the furnace was increased to over 200 tons. Since the time required for refining a large charge in a large furnace is no longer than for a small one, the former is more economical in labor, fuel and repairs.

The important points to be observed in softening are to melt the charge at a low heat and remove the dross that accumulates on the surface, which contains the greater part of the copper.

DAVID WESSON, PRESIDENT OF SECTION ON FATS, FATTY OILS, AND SOAPS.

Next, to increase the heat and admit air for the purpose of oxidizing arsenic and antimony. The oxides of these metals are then skimmed. In some cases pure litharge has been added for the purpose of oxidizing the impurities.

The next step consists in desilvering with zinc. It is of great importance that the zinc be well incorporated with the lead bullion. At first this was done by hand stirring and later by passing dry steam into the charge. Both of these methods, however, have given way to the mechanical stirrer invented by W. H. Howard, which consists of a propeller wheel which thoroughly mixes the zinc with the bullion.

For removing the silver crust a special press is now used which also was invented by W. H. Howard.

The desilvered lead is finally freed from the remaining zinc by oxidation in a reverberatory furnace at high heat. Steaming in kettles has been used, but it is now abandoned in favor of the reverberatory.

The refined lead is tapped from the kettle and conducted through a swinging 1½-in. pipe to molds arranged in a circular position, the flow being controlled by a cast-iron cock. The latest improvement in molding the lead is the molding machine introduced at the National Lead Works by Mr. A. Oechsler. This is especially adapted for handling large charges economically.

In distilling the zinc crust, the first operators made no effort to condense the zinc; later the custom was adopted of mounting a crucible in an inclined position in a coke furnace and condensing the distilled zinc outside. When the charge was finished the crucible was handled with tongs and emptied. In 1870 A. Fabre du Faure mounted the retort in the furnace so that by tipping the latter the retort could be emptied. This is used by practically all lead refiners to-day.

Greetings from Germany. At the close of the session Dr. F. Heberlein formally presented greetings and best wishes from the Gesellschaft Deutscher Metallhütten-und Bergleute in Berlin.

Mr. G. C. Stone spoke briefly on behalf of the American Institute of Mining Engineers, offering the services of the Institute to visiting members, and inviting them to make use of the Institute library and building.

The First of the General Lectures at the College of the City of New York

The Lecture by the Representative of France.

It was characteristic of the international magnitude of the Congress that men pre-eminent in the profession of applied chemistry should be invited to deliver the important general lectures which followed the sectional meetings of each day. For these positions of honor there was selected a representative from each nation represented in the four official languages of the Congress, namely, French, German, Italian and English. A beautiful setting was provided for these special functions by holding them in the Great Hall of the College of the City of New York, where a brilliant assemblage of members and guests of Congress listened to the latest achievements in chemical science.

Catalytic Fertilizers

The first of these general lectures was given Friday afternoon, Sept. 6, by M. Gabriel Bertrand, professor of biological chemistry at the Sorbonne and the Pasteur Institute, Paris, France. The professor delivered his lecture in French, and took for his subject "The Part Played by Infinitely Small Quantities of Chemicals in Biological Chemistry." His remarks had special reference to the chemical food of plants, and bore directly on the improvement of the great industry of agriculture.

We have been accustomed to thinking of the chemistry of plants as comprising the compounds of carbon, oxygen, hydrogen and nitrogen, and have regarded the combinations of nitrogen, potassium and phosphorus as the only essential plant foods. Years of study and experiment, however, have shown Professor Bertrand that the composition of plants is very complex and that at least thirty of our eighty or more chemical elements enter into plant life.

Amongst these constitutive bodies some are found in extremely minute proportions, inferior in certain cases to 1/100,000 of the living plant's weight. It is interesting, not only from a theoretic point of view, but even a practical one, to know whether these infinitely small chemicals play a useful part in the plant's life.

On the assumption that a plant becomes stunted when any one of its chemical foods is lacking, Professor Bertrand conducted investigations to ascertain the actual need of these infinitely small quantities of chemical elements. Particularly in the case of manganese did he find remarkable effects from withholding or adding this element to the plant food.

The plants contain a substance (named Laccase, because it was first extracted from the lacker trees) which produces, at least in part, the fixation of the atmospheric oxygen. That element, which is necessary to the plant's life, is due to the combination of a minute quantity of manganese with this

organic substance playing the part of a weak acid. That is the reason why manganese is truly a physiological element and must be introduced into the soil with the manure whenever it is missing.

Cultural experiments have proven that a minute proportion of manganese may increase the crops to a large extent, and that a small expense thereupon may secure, in certain cases, worthy benefits.

By generalizing this method it has been shown that several other chemical bodies of which plants contain minute propor-

MAXIMILIAN TOCH, PRESIDENT SECTION ON PAINTS, DRYING OILS AND VARNISHES.

tions can supply a new list of manures, named "Catalytic manures," and these are capable of modifying to advantage the fertility of soils and of increasing thereby the wealth of nations.

Following the lecture, Dr. William H. Nicholls, president of the Congress, asked Sir William Ramsay to thank Professor Bertrand officially for coming to this country and delivering his wonderfully interesting lecture. In doing so, Sir William pleasantly reminded the audience that while it was von Liebig who discovered the meat and bread of plants, it had remained for Professor Bertrand to find the piquant sauce which added relish to the substantial food. A vote of thanks was then moved by Sir William Ramsay, and was seconded by Dr. Charles A. Doremus.

The action was then conveyed to Professor Bertrand by Leclerc de Puligny, personal representative at the Congress of the French Ambassador, and representing also the French Minister of Public Works.

Reception at Metropolitan Museum of Art.

On Saturday night, Sept. 7, a reception was given by the American Chemical Society to the members of the International Congress of Applied Chemistry and to the members of the International Congress for Testing Materials. Through the courtesy of the trustees of the Metropolitan Museum of Art it was held at the Museum, which was beautifully illuminated.

In spite of a thunderstorm the attendance was very large and international. There was a long receiving line comprising the past-presidents of the American Chemical Society and headed by its present president, Dr. Little, and Mrs. Little.

All the halls were beautifully illuminated and guides were on hand to take the visitors through the Museum. There were refreshments and every one agreed that the reception was a most enjoyable affair.

Joint Session of Electrochemical and Metallurgical Sections

On Saturday morning a joint meeting of Sections IIIa (Mining and Metallurgy), Xa (Electrochemistry), and XIb (Political Economy and Conservation of Natural Resources) with the American Institute of Mining Engineers and the American Electrochemical Society was held. President W. Lash Miller of the American Electrochemical Society was in the chair.

Heat Losses in Electric Furnaces.—A paper by **F. A. J. FitzGerald**, of Niagara Falls, emphasizes that in the design of an electric furnace one of the first things to be considered in avoiding heat losses is to make the rate of generation of energy per unit volume of charge as high as is compatible with other considerations, for in this way the saving of heat losses may be largely prevented. A series of experiments was made in which a furnace charge was heated to a certain temperature and the effect of increasing the rate of generation of energy was determined by comparing the kw-hours required to heat a given charge. Here are typical results:

Rate of generation of energy.	Energy per kilogram of product.
88 kw.	1.7 kw-hours.
93 kw.	1.6 kw-hours.

Thus by increasing the rate of generation of energy by 5.7 per cent the energy consumption was reduced 5.9 per cent.

Another point of great importance in furnace design in order to avoid heat losses is to keep the external surface of the furnace as small as possible. In a resisting furnace using 746 kw the charge was heated to a temperature somewhat above 2000 deg. C., and maintained at that temperature for some hours. The furnace as originally constructed had an outside surface of 80 sq. m, excluding the foundation. The design was afterwards changed so that the outside surface was 53 sq. m. Determinations of the energy consumption per kilogram with the two designs of furnace gave the following results:

Surface of Furnace.	Energy per kg. of Product.
80 sq. m.	6.1 kw-hours.
53 sq. m.	5.0 kw-hours.
Reduction 34 per cent.	18 per cent.

Having done all that is possible in the way of perfecting the design of the furnace so as to avoid unnecessary heat losses, the final step is to provide the best heat insulation possible. Experiments were made on the total loss of heat with different kinds of materials mainly used in furnace construction. The furnace used consisted of hollow cubes with sides of 230 mm., while the hollow spaces were cubes with sides of approximately 110 mm., so that the thickness of the walls of the hollow cubes was 60 mm. The furnaces were supported on knife edges so that all sides were exposed to the air. A current was passed through the resistor in the interior of the furnace and so regulated that the temperature was maintained constant. When equilibrium was reached the temperature and rate of generation of energy was noted, this giving the amount of heat escaping through the furnace walls at that temperature.

The results are given in a table and show that "red building brick" and "insulating building brick" are better heat insulators than either firebrick or silica brick or manganese brick. By far the best heat insulator is however Kieselguhr brick. Further, the heat loss from a furnace constructed of firebrick could be reduced to less than one-half by providing the firebrick walls with a special asbestos heat-insulating jacket.

In the discussion which followed Dr. J. W. Richards pointed out that it is important to know the rate at which one can pump energy into an electric furnace. Since the heat losses by radiation are practically constant with the time, the efficiency will be the higher the greater the rate of pumping energy into the furnace. In comparison of the operation of various furnaces, care must be taken to take into account whether a strongly endothermic action takes place in one of the furnaces; if it absorbs considerable energy it would make quite a differ-

ence in the comparison, if neglected. Loss of heat by convection is very little understood and often represents a large serious loss. A furnace should never stand in a draught. Dr. Richards finally mentioned that he had seen in Europe in use in a furnace aluminium nitride bricks. At a temperature of 1600 to 1800 deg. they are excellent heat insulators and also very good electric insulators.

Electric Induction and Resistance Furnaces.—A paper on this subject by **C. H. vom Bauer** on electric induction and resistance furnaces dealt with recent developments of the in-

FRANCIS WYATT, PRESIDENT SECTION ON FERMENTATION.

duction furnace and the Roechling-Rodenhauser combination furnace.

The author discussed briefly the two-phase construction and its advantages over single-phase and three-phase furnaces in electrical as well as mechanical respects. It is possible to produce as high a temperature in an induction furnace as may be desired. The only temperature limit is set by the lining. In a recent test with steel in an eight-ton furnace which was very much overheated indications were obtained of a recalescent point at about 2500 deg. At that temperature the steel became viscous, while some 200 deg. higher it was liquid again.

Roechling-Rodenhauser furnaces are shortly to be built in 16-ton and 20-ton sizes abroad as well as in this country.

Electric Steel Refining.—A paper by **Paul Heroult** of New York City on recent developments in the electric steel furnace points out that the electric steel furnace has now reached a point when the reduction of costs depends entirely on improvements in detail both in furnace construction and manipulation. In Europe the process was developed further for high-priced steels, but in the United States the principal problem has been that of making rails.

At the present time the application of the electric furnace for the manufacture of intermediate steel and all qualities of alloy and special steels is established. By the use of the electric furnace the quantity of blow holes and waste can be reduced to a minimum and saving in the cost of machine work alone would justify paying a very much higher price for electric steel castings, if this were necessary.

In the case of many low-carbon high-quality castings made in the electric furnace, it is unnecessary to anneal them and this makes an additional saving in the cost of manufacture. The following tests were given for ordinary mild-steel castings from an electric furnace:

Analysis: Carbon [illegible], Sulphur and Phosphorus below 0.02

Test No.	Ma. Sq. In.	Area Red. of Area	Elastic Limit Lbs. per Sq. In.	Ultimate Strength Lbs. per Sq. In.	Elongation in 2-in.
56,145	0.44	68.2%	44,000 lbs.	71,440 lbs.	34.00%
56,150	[illegible]	[illegible]	45,850 lbs.	67,600 lbs.	30%

From these figures it will be seen that it is possible to make a mild-steel casting comparing favorably with plate steel, and the question arises whether the working of steel under the hammer or rolling mill can improve its quality in any way whatever if the steel be free from faults and cavities.

Another application of the electric furnace which is of great importance to manufacturers of alloy steel depends upon the fact that any quality of scrap can be worked up and the valuable metals retained. Thus, for example: It is not common in practice to melt up charges of miscellaneous tungsten steel including various tools, turnings, hammer scale and "spillings" from crucibles, all of which contain a certain quality of tungsten. Such a charge can be melted up and the necessary additions made to bring the composition up to the required specification. Chrome, nickel and vanadium steels for automobile work may also be made in this way in the electric furnace by melting up miscellaneous scrap.

With regard to the reduction in cost, which has been effected during the last few years, it may be said that this is almost entirely due to slight improvements in practice and design which are the results of continuous experience. Two years ago it was considered good practice to melt and refine steel scrap in six hours at a power consumption of 750 kw-hours per ton, whereas at present furnaces are working steadily carrying out the same operation in four hours at a power consumption of under 600 kw-hours over periods of six months. Similar reductions in operating expenses have been made in all other details, such as labor charges, refractories, etc. To erect and operate an electric furnace successfully it is essential to have had considerable experience, both in the steel trade in general and in electric furnace work in particular, as the old-established principles of steel making cannot always be followed.

Dr. Heroult's paper, which in the absence of the author had been read by Dr. W. H. Walker, was discussed at some length. Mr. Rogers, of the American Steel and Wire Company, said that from their tests of electric steel it seemed that electric steel was better adapted for rails than for wire products. For wires he felt that they were not justified in the additional expense of electrical refining.

Mr. Brady, of the Illinois Steel Company, said that their company had made electric steel particularly for rails and castings. "So far our steel has given us very great encouragement as to the qualities of electric steel and that is all we can say at present."

Mr. Speller, of the National Tube Company, said that according to their experience electric steel is much better adapted to seamless tubes than to the welded tubes made by their company. Dr. Richards thought that this difficulty in welding of electric steel was undoubtedly due to the lack of intermingled slag in electric steel. An interesting application of electric melting in Norway is the melting up of steel scrap from dismantled ships. Although electric energy is quite cheap there ($8 per h.p. year) they have found it preferable to use the electric heat only for the higher range of temperatures and employ fuel heating for the lower temperature range, coal being imported from England at $4 a ton and used for making producer gas.

Electric Heating and the Removal of Phosphorus from Iron.

A paper by **Albert E. Greene,** American Electric Smelting & Engineering Company, Chicago, Ill., suggesting new possibilities in removing phosphorus from iron, and thereby making available for use the high-phosphorus iron ore.

The various reactions of phosphorus associated with iron may be summarized as follows:

1. At temperatures under 1450° C. phosphorus in pig iron

has greater affinity for oxygen than has the carbon in the pig iron, but less affinity for oxygen than solid carbon in the presence of pig iron.

2. At temperatures above 1450° C. the affinity for oxygen of the carbon dissolved in iron becomes greater than the affinity of phosphorus in the iron and the dissolved carbon can reduce calcium phosphate in the slag, as, of course, solid carbon can do also.

3. Phosphorus oxidizes in presence of lime and iron-oxide to calcium phosphate in absence of silicon or solid carbon.

4. Silicon reduces calcium phosphate nearly always, but there may be a range of temperature under 1450°, where phosphorus oxidizes to calcium phosphate more easily than silicon to calcium silicate.

5. Solid carbon will reduce calcium phosphate contained in a slag or bath of iron and phosphorus will go into metal.

6. Calcium phosphate can form without oxidation of iron in presence of carbon dissolved in pig iron at low temperature.

7. Calcium phosphate can form without oxidation of iron in absence of carbon and silicon at high temperatures, *i.e.*, above 1450° C.

8. Oxide of iron can be reduced without reduction of calcium phosphate contained in some slag.

9. Solid carbon is a stronger reducing agent than carbon dissolved in the iron, probably because of the affinity of the metal for carbon.

It is apparent that in all of the present processes the complete control of at least one important factor is either lacking or has not been utilized. In the open hearth process it is the control of the reducing conditions that is limited and likewise in the Bessemer process; but in this latter process the control is further limited by the necessity of raising the temperature by oxidation of elements in the charge itself. In the electric furnace, however, where heat can be produced independently

FRANK K. CAMERON, PRESIDENT SECTION ON AGRICULTURAL CHEMISTRY.

of combustion or chemical reaction, this important factor—namely, intensity of reducing conditions—can be controlled at will and with ease. Up to the present time this fact appears not to have been appreciated by metallurgists, judging by present methods. It is in the complete control of the reducing conditions that important possibilities of electric heating lie, and as this fact becomes more generally recognized and used it is probable that some method will be devised for measuring the intensity of reducing conditions or equilibrium conditions. Since the intensity of reducing conditions is the reverse of the intensity of the oxidizing conditions, the term "oxygen pressure" may find a use as a measure of them.

Among the reactions made possible by control of the reducing conditions and temperature simultaneously is the reduction of oxide of iron from a slag containing calcium phosphate without reduction of the phosphorus contained therein. Naturally the origin of the phosphorus containing slag or charge is immaterial; it may be raw ore containing phosphorus, or it may be a slag in which some of the original oxide of iron served to provide the oxygen for combination with phosphorus, the oxide of phosphorus subsequently combining with lime to form phosphate. Or the reducing conditions may be so controlling as merely to prevent oxidation of iron which, at the same time, causes phosphorus to oxidize and combine with lime.

In the writer's experiments along this line it has been found that at temperatures below about 1400° the phosphorus was easier to oxidize than carbon from pig iron. And it was found that the phosphorus could be oxidized in the presence of lime without any resultant oxidation of iron and with practically no oxidation of carbon; that phosphorus could be oxidized in the presence of lime without oxidation of manganese, and a very interesting further observation was made—namely, that at certain temperatures between the melting point of pig iron and about 1350° C. phosphorus oxidized in certain cases in the presence of lime without any appreciable oxidation of silicon.

This would indicate a reversal of oxygen affinity of these elements—phosphorus and silicon in pig iron in the presence of lime.

A fusible slag results from proper proportions of acid and basic radicals. It has been found that the silicon content in the slag may be as high as 30 per cent without apparently hindering the removal of phosphorus. Phosphorus was separated in slags containing this much phosphorus, and yet practically no iron oxide was present in that slag.

This points to the possibility of a low melting point slag for holding phosphorus.

The reduction of oxide of iron from a charge of slag containing phosphorus as calcium phosphate without reduction of the latter requires essentially the same control of the conditions as does the selective oxidation of phosphorus in presence of lime forming calcium phosphate, without oxidation of iron.

Electric heating is the only practical way of accomplishing such control.

It is not to be doubted that metallurgists will very soon appreciate the distinction between various degrees of oxidation and reduction, where they have not already done so, since in so many cases undesired elements can be separated from metals by oxidation of the impurity and reduction of the metal.

When this becomes generally appreciated it is prophesied that electric heating will come into use to an extent that can now harly be thought possible.

The Slag in Electric Steel Refining.

A paper by **Richard Amberg**, of the Crucible Steel Company of America, of Harrison, N. J., discussed "the function of the slag in electric steel refining." This function, of course, depends on the kind of work which the furnace is desired to perform, and this depends on the cost of power. In localities where power is cheap, the electric furnace may be used for carrying out reactions which in other places with more expensive power would be carried out more cheaply in an oxidizing furnace like the open-hearth.

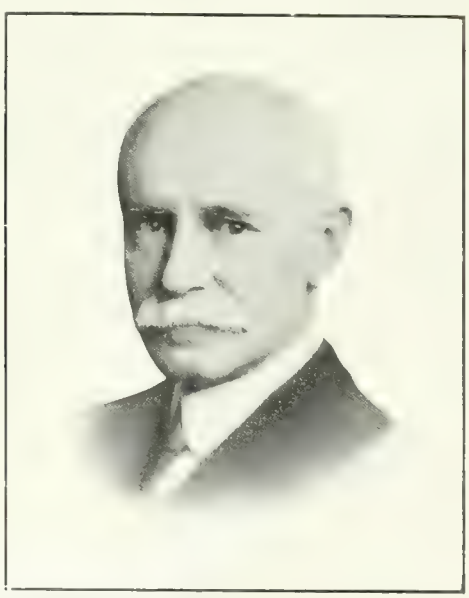
At places where cheap power is available, electric steel melting begins with the widely known open-hearth process of melting pig and scrap. Assuming a basic-lined bottom and hearth heated by one or more electric arcs, the charge melts down, slag is formed by lime, silica, and iron-oxide in the form of ore

of scale, and the refining by oxidation takes place in form of heterogeneous reactions of different kinds. After the ferric oxide dissolved in the slag has been reduced to ferrous oxide, it partly acts directly on those parts of the metallic solution which come in immediate contact with it, and partly dissolves in the metal according to temperatures and coefficient of division of FeO between the two liquid phases (metal and slag). If the slag is saturated with FeO, the latter can assume its full concentration in the metal bath according to the solubility curve. Its action there on manganese and the metalloids is much the same as in the open-hearth. It can be more energetic, however, if the operator avails himself of the facility of a higher temperature, which is a special feature of the electric furnace, and of a higher concentration of FeO.

There is one essential difference from the reactions in an open-hearth slag. In a well-built electric furnace, practically all the oxygen required has to be supplied in solid oxide form, while the open-hearth has an unlimited supply of oxygen in the air supply.

At this period of oxidation the basic slags of an arc furnace and of an induction furnace show a material difference; the dephosphorization, being a process which reaches its maximum velocity at a temperature somewhat below the melting point of soft iron, is accomplished more quickly in the comparatively colder slag of the induction furnace than under the higher heat of the arc. The technical significance of this fact, however, is small.

The analysis of the slag during this period does not offer any particular interest in comparison with open-hearth slag. CaO will run in the neighborhood of 40 per cent, sometimes 5 to 8 per cent lower, iron and manganese oxides 26 to 29 per cent together, and the silica will vary with the silicon of the charge, and the additions. P_2O_5 may run up to any amount in crude open-hearth work, yet, as a rule the slags have been skimmed, when it reached something like 4 per cent. As manganese ore,



W. P. MASON, PRESIDENT OF SECTION ON HYGIENE.

even at this stage, helps desulphurization, it seems to act locally, perhaps near the electrodes only.

As explained before, this dephosphorization period may be carried out in an ordinary non-electric furnace. When it is finished, then begins an entirely new operation, the deoxidation of the metal. This involves a slag process which none of the other furnaces can perform. Carbon is the chief deoxidizing agent and is bound to act in both phases.

Electric heating, as described in the patents of Humbert, offers the possibility to heat the slag with the addition of carbon in a reducing atmosphere so quickly that it forms a high endothermic compound of calcium and phosphorus, probably Ca_3P_2, which is not reabsorbed by the steel phase; hence the opportunity to dephosphorize without skimming the slag. How sensitive this reaction is with respect to temperature is shown by the fact that without very accurate control of the temperature a rephosphorization of the metal has been found.

Since in the reducing atmosphere, when carried on far enough, the partial pressure of oxygen is very low, the oxygen can be removed to a considerable extent from both phases without disturbing the equilibrium at the contact surface, while the opposite would be the case with an open-hearth furnace. In fact, the amount of FeO present in the final slag is easily brought down in everyday practice to between 1 per cent and 0.5 per cent, and with a little attention considerably lower. The reaction, by which this is performed, is a true heterogeneous one (that is, a reaction between the metal and the slag at the points of contact) and consequently does not come to an equilibrium in the original phase; FeO as a base of the silicates or as dissolved in the slag is freed from oxygen and the metal joins the other phase. Manganese is practically removed from the slag in a similar way. Even silicon is partly reduced, when the basicity of the slag and the temperature are both high enough.

The desulphurization has been the subject of many experiments and discussions.

In the oxidizing period, where sulphur is being removed only to a small extent in the open-hearth, the electric furnace is much more efficient in this respect, especially when manganese ore is used. It is likely that a good bit of the sulphur forms SO_2 and disappears with the gases, as the partial pressure of O and SO_2 in the atmosphere of the electric furnace is smaller than in the open hearth, the reaction takes place more easily.

In the reducing period a new desulphurizing action takes place, according to Dr. Amberg, as follows:

(1) $FeS + CaO + C = Fe + CaS + CO$ at the high temperatures of the arc furnace.

(2) $2\,CaO + 3\,FeS + CaC_2 = 3\,Fe + 3\,CaS + 2\,CO$ at still higher temperatures, where calcium-carbide can be formed.

(3) $2\,FeS + 2\,CaO + Si = 2\,Fe + 2\,CaS = SiO_2$ at the lower slag temperatures of the induction furnace.

(4) $CaS + FeO = FeS + CaO$. This equation occurs from left to right for comparatively small amounts of oxygen, while from right to left it is the underlying principle of the three reactions, 1 to 3.

In all the foregoing reactions one feature deserves the most important consideration, that is, the high basicity of the slag; this, in turn, is made possible by the high temperatures attainable, especially in the arc furnaces.

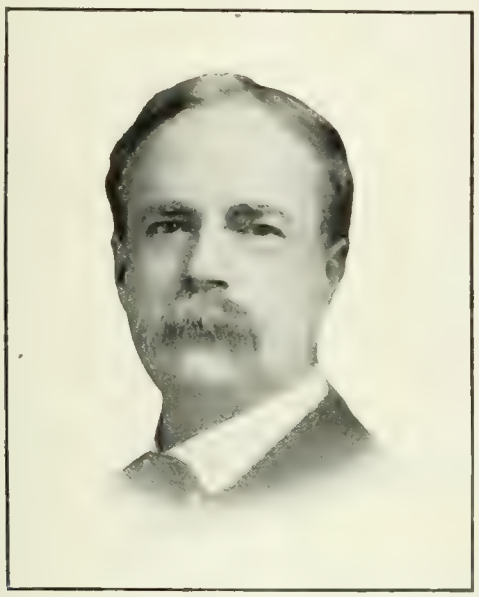
The elements which in the present electric furnace practice take care of reducing the oxides are chiefly carbon in the arc furnace and silicon in the induction furnace. The manganese is practically eliminated altogether, the FeO easily removed down to 0.5 per cent FeO, nickel is reduced with great ease, chromium, tungsten and vanadium according to their inherent amount of free energy with a larger consumption of power.

To explain the mechanism of the reactions it is best to consider them as reactions in a system of different phases (two liquid, metal and slag, the third gaseous, and the fourth, namely, the hearth of the furnace, solid). It is of great importance for the advancement of general metallurgical knowledge to determine the melting points of the pure compounds and give the complete diagram of the melting point of their mutual solutions over as wide a range of concentrations as possible. Much remains to be done in this field. Some important melting points are as follows: $FeSO_3$, 1050 deg. C.; $MnSiO_3$, 1150 deg. C.; $CaSiO_3$ 1220 deg. C. to 1225 deg. C.; $MgSiO_4$, 1400 deg. C.

The carbon thrown into the furnace and the carbon derived from the electrodes can produce several compounds. Prevalent among these are silicon carbide, calcium silicide, and calcium

carbide. This latter one seems to be the most persistent under operating conditions and is recognized by the development of acetylene from a cooled-off sample. It is only after this carbide has been formed to a certain extent that the deoxidation of the charge can be relied upon as completed.

When this condition of the bath has been realized, the electric furnace represents the nearest approach to the ideal hetereogeneous equilibrium between the different phases which has hitherto been accomplished in large-scale metallurgy; converter and open-hearth are under the action of air and gas, the crucible metal takes carbon and silicon up, while in the electric



J. P. REMINGTON, PRESIDENT OF SECTION ON PHARMACEUTICAL CHEMISTRY.

furnace the action of the metal on the basic lining is almost nil, while there is no exchange of elements between metal and slag. However, a small evaporation of participants of the slag takes place, and in this respect the induction furnace with its cold slag has a slight advantage over the arc furnace.

Under certain working conditions of operation of an arc furnace, when it is thought advisable not to cover the electrode holes in the arc airtight, fumes can be seen passing through the small joint between electrode and roof brick. These fumes always leave a deposit on the cooler parts of the electrodes, in powder form. An analysis of them taken during the oxidizing period of a furnace showed, aside from minor quantities of other substances, SiO_2, 4.50 per cent; FeO, 8.49 per cent; Fe_2O_3, 60.60 per cent; CaO, 8.10 per cent. This composition allows the conclusion that after reducing the metallic oxides from the slag there will be a considerable volatilization of CaO and some less volatilization of SiO_2, both being probably first volatilized as elements and then oxidized in contact with the atmosphere. Smaller lots of Si may perhaps take part in the desulphurization by forming SiS_2, a volatile compound, and then decompose in contact with humid air or water.

The author then takes up the physical aspect of the fact that there is by no means an ideal two-dimensional contact surface between slag and metal and that both phases penetrate each other to a considerable extent. The prevailing picture that slag and metal behave like oil and water is only relatively true. The slag swims on the metal, but where small parts of the one are caught in larger masses of the other, they have to overcome an enormous friction in order to be separated, and the smaller the slag particles the more difficult is their separation from the metal bath. It is, therefore, very important to keep the finished charge quiet and at a sufficiently high temperature to allow it to settle. Hereafter proper precautions have to be taken while teaming and pouring that the painstaking results of refining might not be reversed.

This slow physical action may furnish a new explanation for the slow progress of the desulphurization according to equation 2. The microscope shows that siliceous and sulphidic products are sometimes contained down to two-thirds, and even lower, from the top of an ingot. These non-metallic products appear as balls in the ingot structure and are elongated into a cigar-like shape after rolling or forging the metal. Although the melting point is lower than that of steel, they have not succeeded in uniting with the bulk of the slag in proper time. Consequently there is a lack of material in the slag, and desulphurization can only take place whenever new sulphides are supplied. As the slag of the electric furnace allows to hold the metal, the sulphur can be removed to any desired extent.

The author concludes with a brief discussion of the acid-lined electric steel furnace. An acid lining requires an acid slag to keep the hearth in good condition. This acid slag will be much the same as the slag of an acid open-hearth as long as the charge is treated with an excess of oxides and the heat not exaggerated; if necessary it can be made to contain a higher percentage of SiO_2 for the same reasons which hold good for highly basic slags. The great difference from the basic electric furnace is, in this case, that all four phases are in lively reaction with each other, that conditions approaching a status of equilibrium can not be reached and that the metal must be "caught" at a certain moment of teaming.

The solid and the metal phase react in this way, that carbon of the bath reduces Si from the hearth, the amount of Si present being regulated by a reaction between the two liquid phases, namely, by keeping a sufficient stock of oxides in the slag to hold the Si within the required limits. The slag will therefore be a thoroughly black one, particularly during the beginning of the run. Thallner ascribes a specific beneficent effect to this exchange of Si and to the low heat canductivity of the silica lining. Towards the finishing of the acid heat the color of the slag clears up, and its reduction finally reaches a point where the glassy masses become light gray and green colored. Sulphur will, as in the acid open-hearth, remain unaltered in quantity, while phosphorus may be slightly decreased by phosphoric acid being thrown out of solution by the stronger SiO_2 and then reduced to phosphide of iron. This has to be confirmed, however, and it has to be explained how this reaction can take place. Nothing definite can be said about it at the present time.

It may be that some of the advantages of this method are due to the mechanical property of the slag to agglomerate more easily than the basic slag particles to larger globules which force their way up to combine with the bulk of the slag.

The paper elicited quite an extended discussion. Dr. Richards called attention to the discussion at the Congress for Testing Materials on the effect of slag enclosures in steel. The contributions presented at this Congress by those who use and test the steel should be carefully considered by the manufacturers of steel.

As to the control of microscopically disseminated particles of slag in steel Dr. Richards made the following propositions. First, to regulate the composition of the slag carefully. Second, to heat the metal in the furnace after the furnace reaction proper is over, for some time in order to let the emulsion separate. Dr. Richards referred to the practice of a Bessemer works in Germany where the metal is permitted to rest after the blow is concluded for considerable time. Of course, the cost of this is high. He thinks the final solution will be to let the metal from oxidizing furnaces rest in an electric furnace for a definite length of time. The electric furnace does nothing else but keeps the metal at a high temperature and permits the slag particles to separate from the metal.

Mr. S. Larsen discussed briefly the removal of sulphur.

Mr. Rogers agreed that by heating the metal in the furnace

and in the ladle as long as permissible a marked influence would be effected on the slag enclosures, but this delay means an enormous expense. To his former remark that electric steel seems more suitable for rails than for wire and that they do not feel justified to substitute electric steel for open hearth steel for wire making, he added that there were two reasons for it. First, the increased cost, and second, the difference in the

W. D. BIGELOW, PRESIDENT SECTION OF BROMATOLOGY.

working of the open hearth steel and the electric steel. The difficulties in working, he said, may be due to their inexperience with electric steel.

Dr. Richards said that the additional cost of heating the metal to let it rest and let the slag separate was not so important if a "holding" electric furnace was used. The cost would be about 25 or 50 cents a ton. The tests of the engineers have shown that the enclosures of slag are very important.

Mr. E. R. Taylor referred to the use of a pig iron mixer and thought that an electric steel mixer for letting the metal rest might be the solution.

Mr. Speller said that the time required for letting the metal rest would be a serious objection. He thought they had found a partial solution in controlling the condition of the slag when the metal leaves the furnace and in a subsequent circulation of the metal in the ladle.

Dr. Amberg said that in wire products where there is a stretching in a longitudinal direction the effect of slag enclosures might not be so important but that for other purposes the slag enclosures were very serious. This might account for Mr. Rogers' conclusions.

Electrolytic Extraction of Copper from Sulphide Ores.—In an informal paper by **J. O. Handy,** of the Pittsburgh Testing Laboratories, Pittsburgh, Pa., an account was given of some experiments on the extraction of copper from sulphide ores by roasting, leaching and electrolytic deposition. The speaker described briefly the method of roasting the sulphide ore to sulphate in a reverberatory furnace and discussed the element of the degree of fineness to which the ore must be ground.

In electrolysis carbon anodes will not do since they are rapidly disintegrated, but lead anodes packed in a fabric are suitable. They produce 23 pounds of copper per h.p. day. An advantage of the process is that a pure product is obtained right away, the cathodes being of high purity containing no arsenic, etc. A disadvantage of the process is that the silver and gold are lost.

The paper was discussed by Dr. Miller and Dr. Richards. The latter called attention to the importance of Prof. Hofman's paper on roasting temperatures presented the day before in the Section of Mining and Metallurgy in a joint session of the American Institute of Mining Engineers.

Dr. Hering referred to his process of depositing zinc out of solution with the aid of spongy lead plates (like the negative plates of a storage battery) as anodes. They prevent the formation of sulphuric acid on the anode, the SO_4 ions being caught by the spongy lead and forming lead sulphate as in the storage battery. When all the spongy lead in the storage battery has been changed to sulphate the plate is removed and placed in another tank where it is discharged and H_2SO_4 is produced. He got a very high extraction of zinc from a zinc sulphate solution by this method.

Section on Analytical Chemistry.

The opening meeting of Section I, Analytical Chemistry, was held Friday morning, September 6, at 10 o'clock, in Kent Hall.

The Action of Boiling Sulphuric Acid on Platinum.—A paper by **Le Roy W. McKay,** of Princeton, N. J., giving the following conclusions:

1. Boiling concentrated sulphuric acid dissolves platinum in considerable amounts.

2. Since the platinum dissolves fully as readily when the interaction takes place in a current of an indifferent gas, such as carbon dioxide, as it does when the experiment is made in air, the oxygen of the latter cannot be concerned in the change.

3. The presence of excess of sulphur dioxide, generated by the interaction of the hot acid and sulphur or carbon, or introduced through a tube into the boiling acid, inhibits almost entirely its solvent action. Sufficient arsenious oxide dissolved in the acid likewise serves to protect the platinum, and even antimonius oxide manifests marked protective powers.

4. If we assume that at the temperature of attack there is a slight but appreciable dissociation of sulphuric anhydride into sulphur dioxide and oxygen, and that it is this oxygen which is responsible for the solution of the platinum, the rôle played by the reducing agents would seem to consist (1) in a repression of the dissociation of the sulphuric anhydride on account of the high concentration of the sulphuric dioxide, and (2) in the arsenious and antimonius oxides consuming the oxygen as fast as it is set free, arsenic and antimonic oxides being formed.

The Measurement of Temperatures in the Operations of Analytical Chemistry.—A paper by **Theodore W. Richards,** of Harvard University, Cambridge, Mass., giving in a few words a statement of the most convenient methods or determining temperature suitable for work in analytical chemistry. The mercury thermometer, carefully constructed and calibrated, and used with proper precautions, has been advocated as the most convenient means at the disposal of the analyst; and a method of making very satisfactory mercury thermometers is briefly described. Further, the wide application of the thermometer in several forms of analytical work has been emphasized.

The Control of Temperature in the Operations of Analytical Chemistry.—A paper by **Theodore W. Richards,** of Harvard University, Cambridge, Mass.

The control of temperature is a very important question in the work of the analytical chemist. The reason is at least threefold. In the first place, temperature affects greatly the speed of all chemical reactions, which are generally accelerated, to extents varying from perhaps 7 to 12 per cent, by each degree's rise in temperature. In the second place, temperature affects the final equilibrium attained by many reacting systems, and therefore influences both the yield and the composition of the products dealt with by the analyst. In the third place, accurate physical measurements, to which the quantita-

tive experimenter must frequently resort, such as weighing the measurement of the volumes of gases and liquids and the determinations of calorimetric or electrical magnitudes, demand considerable control of temperature if any accuracy is sought.

Nephelometry.—A paper by **Theodore W. Richards,** of Harvard University, Cambridge, Mass.

The Nephelometer is a simple and generally applicable piece of apparatus for estimating traces of suspended precipitates in liquids. The determination is effected by measuring the brightness of the light reflected by the suspended particles; from the amount of this reflected light the weight of suspended material may be inferred with considerable accuracy, provided that the proper precautions are taken concerning the standard of reference. The device is a great convenience for finding exceedingly small quantities of material too finely divided to be collected upon a filter and determined gravimetrically.

The Specific Gravity Balance for Solids.—An illustrated descriptive paper by **A. H. Sabin,** of Brooklyn, N. Y.

Volatility of Arsenous Chlorid.—A paper by **J. I. D. Hinds,** of Cumberland University, Lebanon, Tenn., giving the following conclusions:

1. That the quantity of arsenous ion lost on boiling its hydrochloric acid solution is a function of the concentration both of the arsenic and of the acid.

2. That when the concentration of the acid exceeds that of the arsenic, the fraction of the arsenic lost on boiling approaches a constant value.

3. That with the concentrations usually employed in qualitative analysis the loss of arsenic on boiling the solution even half away is generally less than one thousandth of the quantity present.

A Study of Some Methods for the Determination of Aldehydes.—A paper by **B. G. Feinberg,** of Columbia University, New York, N. Y.

The Detection and Estimation of Exceedingly Minute Quantities of Carbon Dioxide.—A paper by **Herbert N. McCoy** and **Shiro Tashiro,** of the University of Chicago, Chicago, Ill.

W. D. BANCROFT, PRESIDENT SECTION ON PHOTOCHEMISTRY.

Rational Analysis of Nitrate of Soda. The Use of the Davarda Method vs. the Misleading "Refraction" Method.—An illustrated paper by **Walter S. Allen,** of Laurel Hill, N. Y., describing and illustrating an apparatus used, and giving the following conclusions:

The inaccuracy and uselessness of the so-called "Refraction" test for commercial nitrate of soda is shown both by a series of complete analyses of this material and by the analysis of 69 samples by both a direct and indirect (refraction) method. The "Refraction" test takes into account only the H_2O, NsCl, Na_2SO_4, and water insoluble matter present and takes no account whatever of potassium salts, chlorate, perchlorate, iodate, lime, magnesia, etc. The complete analyses show that it is only by taking into account all these impurities that a reliable value for $NaNO_3$ can be obtained.

The only rational procedure is to discard entirely the misleading "Refraction" method and substitute therefor a direct method—the same to be used on a basis of valuation in all contracts.

Section on Explosives.

The opening meeting of this section was the occasion of the presidential address by **Charles E. Munroe,** entitled **The Development of the Explosive Industry in the United States During the Last Three Years.**

Following this address the regular program was taken up.

Methods for the Determination of the Effective Strength of High Explosives, by **Arthur M. Comey** and **Fletcher B. Holmes.** This was followed by another paper by the same authors, entitled **The Use of the Ballistic Mortar for Determining the Strength of Explosives.**

In the afternoon **Dr. Bernhard Flurscheim,** of Hampshire, England, described a new high explosive of recent discovery known as **Tetranitroaniline.** The speaker gave the results of firing this explosive and some mixtures in a large bomb from which the air had been exhausted.

Alfred L. Broadbrent and **Fin Sparre,** of the Du Pont Powder Company, Wilmington, Del., gave the results of some experiments on the nitration of anisol to trinitroanisol. In the next paper the hydrolysis of the latter substance was discussed by **W. E. Masland** and **Fin Sparre.**

The Preparation, Crystalline Structure and Physical Properties of the Two Forms of Solid Nitroglycerine.—A paper by **Harold Hibbert,** of Wilmington, Del., in which the author shows that solid nitroglycerine exists in two forms, possessing different freezing and melting points. They showed photomicrographs of both substances.

Following this paper **A. L. Kibler** presented a discussion of the hydronitrides and the synthesis of mercury fulminate from propyl alcohol. At the close of the meeting **V. Watteyne** presented the final report of the International Committee on the Unification of Methods for Testing the Stability of Explosives.

Section on Hygiene.

The Friday program of the section devoted to Hygiene was postponed for consideration on Saturday, September 7. With a few exceptions the papers presented dealt with the subject of hypochlorites in the sterilization of water.

Examples of the Efficiency of Calcium Hypochlorite in Treating Turbid Waters, by **Edward Bartow,** University of Illinois, Urbana, Ill., who recently had the privilege of noting the action of calcium hypochlorite in the purification of turbid waters in some of the plants in the North Central United States. Results from two of the plants illustrate in different ways the efficiency of the chemical. In one case the chemical was added at the end of a long sedimentation period, during which some reduction had taken place. The chemical reduced the number of bacteria very materially and filtration was able to effect a still greater reduction. In the other case, owing to failure to receive a shipment of the chemical, none could be used for six days. There was at once a decided increase in the number of bacteria, followed by a decrease when the chemical was again applied, even though the water, as shown by the turbidity, was the worst for years.

Sur la Sterilisation des Eaux Potables, by **H. Hinard,** Paris France

Epuration des Eaux Residuaries de Peignages de Laines, by **E. Rolants,** Chef du Laboratoire d' hygiene d' l' Institut Pasteur de Lille.

In addition to these papers there were other addresses:

The Water Supply of Farm Homesteads, by **Frank T. Shutt.**

The Use of Hypochlorite in Checking a Mild Typhoid Epidemic of Evanston, Ill., by **W. Lee Lewis.**

The Factors Conditioning Velocity Disinfection, by **Harriette Chick.**

The Hypochlorite Sterilization of Water Supplies as Accomplished in Several Cities, by **C. A. Jennings.**

Section on Pharmaceutical Chemistry.

After the formal organization and opening of the section devoted to Pharmaceutical Chemistry, the first business transacted was the reception of a report of the commission on **Variations in the Activities of Toxic Drugs,** by **William Mair,** Edinburgh, Scotland. The regular program was then taken up and the following papers were presented, either by the author or announced by title.

Belladonna, the Effect of Cultivation and Fertilization on the Growth of the Plant and on the Alkaloidal Content of the Leaves, by **Francis Ransom** and **H. John Henderson,** Hitchin, England.

The Alkaloidal Content of Individual Plants of Datura Stramonium L. and Datura Tatula L., by **F. A. Miller** and **J. W. Meader,** Indianapolis, Ind.

The Potency of First Year Cultivated Digitalis Leaves as Indicated by Physiological Assay, by **F. A. Miller** and **W. F. Baker,** Indianapolis, Ind.

The Effect of Cultivation Upon the Alkaloidal Content of

W. R. WALKER, PRESIDENT SECTION ON ELECTROCHEMISTRY.

A. Belladonna, by **Francis H. Carr,** Dartford, Kent, England.

A Study of American Grown Cannabis in Comparison with Samples from Various Other Sources, by **C. R. Eckler** and **F. A. Miller,** Indianapolis, Ind.

Section on Organic Chemistry.

The first meeting of this section was held Friday morning, September 6th, in Kent Hall. Among the interesting papers presented was one entitled **An Electric Still Adapted for Difficult Distillations,** by **Irving C. Allen,** of the United States Bureau of Mines, Pittsburgh, Pa. The author was led to devise this still on account of the uneven heating obtained in ordinary stills.

In the device under consideration, the heater consists essentially of two pear-shaped halves of heat-resisting materials inclosing and closely fitting the retort or distilling flask. The halves hold on their inner or concave surfaces a metal resistance wire, wound back and forth for conducting an electric current. The electrically heated wire warms the flask and its contents, and boiling proceeds quietly, uniformly, and most satisfactorily.

Construction of the Still.—The body of the heater is composed of 100 parts by weight of powdered magnesia, 100 parts by weight of powdered silica, 40 parts by weight of finely shredded asbestos, and 10 parts by weight of powdered sodium silicate, thoroughly mixed together, dry, and made into a paste with a 10% aqueous solution of magnesium chloride. The use of this paste was suggested by Mr. A. V. Bleininger, formerly ceramics chemist of the United States Geological Survey. The paste may be molded into any form desired, and after setting over night it becomes hard and firm enough to endure gentle handling.

To prevent cracking and warping during the subsequent drying, the heater is warmed in an oven at about 50° C. for 48 hours, after which it is heated at 200° C. for several hours to expel the last traces of moisture. The heater is then hard and sufficiently strong for most laboratory purposes. It will endure heating, without corrosion of the wire and without injury to the insulating material, to the temperature at which the glass of the retort begins to soften, the highest temperature to which the heaters in the Pittsburgh laboratory have as yet been subjected.

Wiring the Heater.—The manner of wiring the heater for a distilling flask is most important. Wrapping the wires equidistant from one another from the bottom of the flask up to the top of the neck develops too great a heat in the neck and in consequence causes superheating of the heavier oil vapors.

Wrapping the wires from the bottom of the flask up to the base of the neck results in a dephlegmatory action in the neck that cannot be controlled.

Mold for Heater.—The forms for a distilling flask may conveniently be made as follows:

Turn from a block of wood a model the size and form of the distilling flask, with the bulb and neck in one piece, and saw the model into halves from top to bottom. Hollow out the bulb and neck to form a shallow dipper, making the cavity about 1 cm. deep, and leaving the rim about 3 mm. thick. Drill holes the size of a small wire brad 1 cm. apart and 3 mm. below the edge of the rim of the dipper and along the handle or neck as far as it is desired to have the heating wire. Insert brads through these holes from the inside and allow the points to project about 3 mm., thus forming a comb of brad points around the outside of the dipper near the edge, Fig. 1, *a*.

Then, after greasing well the convex surface of the mold to prevent the paste from sticking, wrap the heating wire back and forth, the wires being 1 cm. distant from one another, across the convex surface of the dipper between these points, in the manner shown in Fig. 1, *a*, tying the wire in place with asbestos cord and making its two ends fast to binding posts projecting at convenient positions. Lay the wired form, convex side up, on a smooth board covered with a sheet of paper and apply freshly prepared paste to the desired thickness, about 2 cm.

Allow the paste to harden over night. Remove the brads from the inside of the mold. The heater will then be released and ready for the final drying described above. Do not pass a current through the wire until the heater has

been thoroughly dried, else rapid corrosion of the wire will result.

A ⅛-liter heater requires about 500 gm. of material and 3.5 meters of wire; a ¼-liter heater about 1000 gm. of material and 5.5 meters of wire, and a 1-liter heater about 2000 gm. of material and 11 meters of wire.

The completed heater is shown at **b** in Fig. 1.

The following program was then carried out, some of the papers being read only by title or presented by representatives of the authors.

A Study of the Lassigne Reaction. S. P. Mulliken and **C. L. Gabriel.**

W. R. WHITNEY, PRESIDENT SECTION ON PHYSICAL CHEMISTRY.

The Electron Conception of Valence, III, Oxygen Compounds. J. M. Nelson and **K. G. Falk.**

The Change in Refractive Index with Temperature, III. K. G. Falk.

On the Mechanism of Organic Reactions. S. F. Acree.

The Molecular Rearrangement of Triphenylmethyl-Hydroxylamine. J. Stieglitz, G. Reddick and **P. Leech.**

The Molecular Rearrangement of Triphenylmethylbromamine. J. Stieglitz and **I. Vosburgh.**

The Reactions of Certain Fumaroid and Maleinoid Compounds with Aromatic Amines. W. H. Warren and **M. R. Grose.**

Die Zusammensetzung der hochsiedenden Mineraloele. J. Marcusson.

Influence des Substituants sur l'action du benzene et de quelques benzenes substitues sur le chlorure de benzoyle en presence du trichlorure d' antimoine. B. N. Menschutkin.

Ethyl Ether by Catalysis. C. Baskerville and **W. A. Hamor.**

Contribution to Our Knowledge of the Condensation Reaction by Means of Anhydrous Aluminum Chloride. Part 1. The Action of Chloral and Aluminum Chloride on the Phenol Ethers. C. B. Frankforter and **W. Kritchevsky.**

A Catalytic Decomposition of Some Phenol Silver Salts by Alkyl Iodides. W. H. Hunter, E. A. Daniels, A. O. Olsen and **L. Karatz.**

An Improved Apparatus for the Determination of Garboxyl Groups in Organic Acids. W. H. Hunter and **J. D. Edwards.**

Ueber Rizinusoelsaeure. B. Rassow.

Margaric Acid and Its Relations to Palmitic and Stearic Acids. R. F. Ruttan.

Section on Industry and Chemistry of Sugar.

At the first meeting of this section a number of important papers were presented. First on the program was:

The Status of Cane Sugar Manufacture in the Hawaiian Islands.—By **Noel Deerr,** Honolulu, Hawaii.

The rapid growth and remarkable results obtained in the cane sugar industry in the Hawaiian Islands forms a matter of sufficient interest to warrant a short account of the present status of the manufacturing side of the industry.

At the present time there are in operation forty-six factories which produced for the year ending Sept. 30, 1911, 566,031 short tons. The output of the individual factories varied from 595 tons to 55,050 tons.

Summary.—The general status of manufacture may be seen from the annexed summary, which is based on statistics covering over 90% of the output of the last five years. The mean figures are true averages and take into account the different amounts produced in the different factories. The figures except when otherwise indicated refer to percentages of the sucrose in the raw material.

	High.	Low.	Mean.
Sucrose % cane	16.6	11.2	14.4
Fiber % cane	15.0	11.0	12.3
Sucrose obtained by mills	96.8	89.0	93.5
Sucrose lost in bagasse	11.0	3.2	6.5
Sucrose lost in scums	1.0	.03	.2
Sucrose lost in molasses	11.0	5.0	6.5
Unknown losses	4.0	.1	1.3
Sucrose in sugars	90.0	70.0	85.5
Sucrose in sugars per 100 sucrose in juice	94.0	82.0	91.5
Purity clarified juice	92.0	82.0	88.0
Purity sugars	99.0	97.2	98.0
Purity waste molasses	57.0	39.0	45.0
Commercial sugars % on cane	14.7	9.1	12.7

This was followed by a paper on **The Determination of Water in Molasses** by **Charles C. Roberts** of Lansdowne, Pa.

In the determination of moisture in molasses and similar products in air, the analyst is confronted with several difficulties; first, the formation of an external film; second, the effects of oxidation; and third, if the temperature is near 100° C., loss of water of hydration.

At the afternoon session there were addresses in French by **Auguste Aulard** and **T. de Grobert.** A paper by **C. O. Townsend** on **Sugar Beet Seed Growing in the United States** was deferred to a later meeting.

Section on Fats, Fatty Oils and Soaps.

There was but one meeting of this section, devoted mainly to analytical methods of determining fatty substances. **Mr. Frank N. Smalley** discussed the **Determination of Total Fatty Acids in Cottonseed Foots.**

The method described is proposed for a rapid method for the determination of the total fatty acids in cottonseed foots, or soap stock, and similar materials, by a determination of the iodin number of the same, and its conversion into terms of fatty acids by means of an appropriate factor.

The six years' use has proven that the method as used gave on the whole extremely satisfacttory results, and it has only received minor modifications, consisting in using special strength of sodium thiosulphate and iodin solution, so as to simplify the calculation.

Other papers that were read at this section by authors or by title were the following:

Experimental Data on the "Cold Test" of Oil, by **Arthur Lowenstein** and **Louis Beolio,** of Chicago, Ill.

Studies on Lipase by **Yoshio Tanaka,** of the College of Engineering, Imperial University, Tokyo.

Heavy Metal Soaps, Their Formation, and Solubility in Spirits of Turpentine, Linseed Oil and Petroleum Oils, a paper by **Irving W. Fay** and **S. G. Hamilton,** Brooklyn, N. Y., in which the authors reached the following conclusions:

1. Stearates and oleates of calcium, iron, aluminium, zinc, copper and lead and stearate of chromium may be easily prepared in aqueous solution from alkali salts of these acids.

2. Oleates of these metals have as a rule lower melting points than the stearates and are darker in color.

Phot. by Harris & Ewing

CHIEF JUSTICE EDW. D. WHITE, PRESIDENT SECTION ON LAW AND LEGISLATION AFFECTING CHEMICAL INDUSTRY.

3. The stearates and oleates are insoluble in cold petroleum oils, linseed oil and turpentine.

4. All the stearates and oleate of zinc form clear solutions in hot linseed oil, turpentine and kerosene oils.

5. The stearates and oleates in weak solutions in kerosene oils separate as precipitates when cold. Calcium stearate and aluminium stearate and oleate in hot strong petroleum oils turn to clear jellies on cooling; the other stearates and oleates under similar conditions form pastes.

Uber das Unverseifbare des Sesamöles, by **A. Heiduschka,** Universitat Muenchen, Munich, Germany

Section on Paints, Drying Oils and Varnishes.

The opening session of the section, devoted to paints, drying oils and varnishes, was comparatively short.

Gustave W. Thompson delivered an address on the **Coating and Hiding Power of Paints.**

The only other paper presented during the morning was **The Decomposition of Linseed Oil During Drying,** by **J. C. Olsen** and **A. E. Ratner,** of the Polytechnic Institute, Brooklyn, N. Y.

There are various statements in the literature on linseed oil that during the process of drying carbon dioxide is given off. The authors have failed to find the record of any definite experiment indicating the amount of this constituent which is evolved during the drying process. No definite information could be found with reference to the amount of water evolved. Experiments have been conducted to ascertain the increase in weight of linseed oil during drying, the assumption being that this increase in weight is due to the absorption of oxygen. It is evident that if volatile constituents are given off during the drying process, the increase in weight will not give a true measure of the oxygen absorbed.

In order to secure more definite information with reference to this very interesting and important reaction, an experiment was carried out in which pure, dry air was conducted over a weighed amount of linseed oil. The increase in weight of the linseed oil was ascertained and the moisture and carbon dioxide given off was absorbed and weighed so that the total amount of oxygen which combined with the linseed oil could be calculated.

The composition of linseed oil is generally given as follows: Carbon, 76 per cent; hydrogen, 11 per cent; oxygen, 13 per cent.

Neglecting the error due to the volatile oil given off, the linseed oil lost 1.87 per cent of its carbon and 14.73 per cent of its hydrogen.

At the time this paper was written the flask and the absorption tubes had not yet become constant in weight. The experiment will be continued until constant weight is obtained.

It was believed that the results, though incomplete, were of sufficient interest for publication.

Section on Starch, Cellulose and Paper.

The Chemistry of Starch.—By **G. B. Frankforter,** University of Minnesota, Minneapolis, Minn., discussing the physical properties and chemistry of starch, the synthesis of the starch molecule and several substitutes related to starch. The author stated in conclusion that he believes starch offers more opportunities to the chemist for important discoveries than any other group of compounds in the whole realm of organic chemistry. Not only is the chemistry proper of vital importance as offering an almost boundless field, but also the great vital subject of fermentation which is so closely connected with the starch. It is to be hoped that in the near future chemists may give more of their time to the chemistry of starch and especially fermentation. If chemists or botanists with a thorough knowledge of chemistry should devote more of their time to the study of starch, the next decade would see the chemistry of starch completely rewritten.

This was followed by two addresses, the first on the **Origin and Significance of Starch,** by **Ernest C. Clark,** and the second on the **Development of the Wood Preserving Industry in the United States,** by **E. A. Sterling.**

The Effect of Variable Grinding Conditions on the Quality and Production of Mechanical Pulp.—A paper by **McGarney Cline** and **J. H. Thickens,** of Madison, Wis.

Briefly stated, mechanical pulp is produced by pressing sections of log against a revolving grindstone, which may or may not be revolving in a pit of moist pulp. If revolving in thick pulp the hot grinding process is employed; if a large excess of water is used the resultant process is one of cold grinding. The factors which enter into the production of mechanical pulp from any species of wood are:

1. The surface of stone; whether rough or smooth, sharp or dull, or of a coarse or fine grit.

2. The pressure with which the wood is forced upon the stone.

3. The peripheral speed of the stone.

4. The temperature of grinding.

5. The moisture content, weight per cubic foot, and the condition of the wood to be ground.

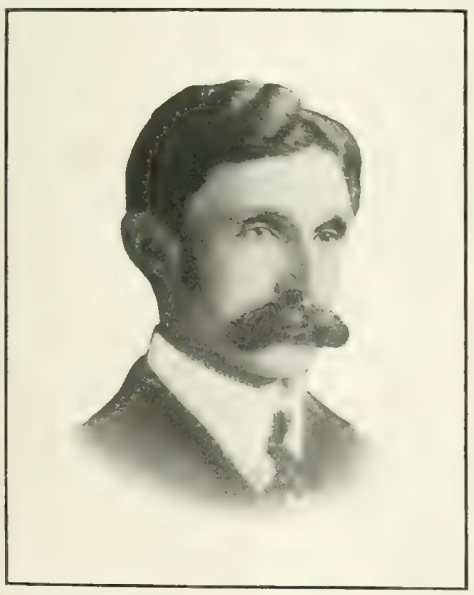
One of the important papers read at the afternoon session was entitled **Tests to Determine the Commercial Value of Wood Preservatives—A Progress Report,** by **Howard F. Weiss,** assistant director, Forest Products Laboratory, Madison, Wis. The author's conclusions were:

The depth to which oils can be impregnated varies as some inverse function of the viscosity. As temperature

strongly influences the viscosity of oils, and as the diffusion of the preservative through the wood is one of the most important factors in proper treatment, it is concluded that to secure best results both the wood and the preservative should be heated to the proper temperature during the pressure period. Because of the low thermal conductivity of wood, the treatments should not be made too rapidly. With water-soluble salts these precautions are not important.

With coal-tar creosote it appears that the fractions of greatest stability are the least toxic. Present practice rather favors the retention in treated wood of the more volatile fractions by an admixture of the more stable ones. If the toxic values here given are correct, there is in practice being forced into wood about two and one-half times as much zinc chloride and fifty times as much coal-tar creosote as is necessary to prevent decay. It is concluded, therefore, that more economic results against decay, especially when it is accompanied by mechanical deterioration, can be secured by diffusing the preservative more thoroughly through the wood than by saturating the outer fibers and attempting to retain in the wood the volatile constituents through admixtures of non-volatile constituents.

In general, the flash or burning point of an oil affects the inflammability of wood treated with it. Of greater importance, however, is the length of time the treated wood has seasoned, as a prolonged seasoning of such wood raises considerably its ignition temperature. It is concluded that it would be good practice to first season such treated timber before placing it in positions subject to fire. While wood treated with the water-soluble salts mentioned in these tests was in general less difficult to ignite than untreated wood, nevertheless the presence of such preservatives almost invariably renders the wood slow burning and easily extinguishable.



J. A. HOLMES, PRESIDENT SECTION ON POLITICAL ECONOMY AND CONSERVATION OF NATURAL RESOURCES.

Other papers read either by author, representative or title were **Bamboo Cellulose,** by **William Raitt,** cellulose expert, attached Imperial Forest Research Institute, Dehra Dun, U. P., India.

In this paper is given a condensed account of the results of an inquiry into the cellulose yielding possibilities of Indian bamboos. Any one desirous of following up the investigation in its full details is recommended to obtain Part III of Vol. III of "The Indian Forest Records," which will shortly be published by the superintendent, Government Printing, Calcutta, and which will contain the official report of the inquiry.

The Paper-Making Qualities of the Hedychium Coronarium, by **Clayton Beadle** and **Henry P. Stevens,** of London, England, giving photomicrographs of fibers and stating that it is possible that this fiber may become of great industrial importance to the paper trade.

The Combination of Starch and Minerals for Paper Sizing was presented by **Hans Wrede.**

Section on Agricultural Chemistry.

The opening session of this section was well attended, and a good program was provided. One of the papers of interest was a **Comparison of Rock Grinding with Balls and Cylinders,** by **R. O. E. Davis,** Bubeau of Soils, Washington, D. C.

The results show that the grinding is best done by the large steel balls. No reason for the use of wrought iron cylinders exists, as the largest amount of material adheres to their surface, the grinding is not so rapid and from the nature of the material, their wear is greatest.

The Radio-Activity of Some Typical Soils of the United States, by **Richard B. Moore,** Bureau of Soils, Department of Agriculture, Washington, D. C., being a preliminary report of the examination of soils from New York, North Carolina and Alabama. The author found no relation between the activities of the soils and their chemical composition except in respect to silica. The amount of rare earths present in the soils was so small that the analytical results were not reliable and no connection could be drawn with them.

The following papers were then presented, either by the authors or read by title:

The Determination of the Permeability of Soils to Water, by **J. Walter Leather,** of Pusa, Bengal, India.

The Relative Effects on Plant Growth of (A) **Sodium Carbonate** and (B) **Imperviousness in Soils,** by **J. Walter Leather,** Pusa, Bengal, India.

Sponge Spicules in Certain Soils, by **R. O. E. Davis,** Bureau of Soils, U. S. Department of Agriculture, Washington, D. C.

The Distribution of Silt and Clay Particles in Soils, by **R. O. E. Davis** and **C. C. Fletcher,** Bureau of Soils, U. S. Department of Agriculture, Washington, D. C.

Remarks on the Theory Concerning the Action of Fertilizers, by **Arthur Rindell,** Helsingfors, Finland.

Concentration of the Soil Solution, by **Frank K. Cameron,** Washington, D. C.

The Rôle of the Lysimeter in Soil Solution Studies, by **Frank K. Cameron,** Department of Agriculture, Washington, D. C.

The Movement of Soil Moisture, by **R. O. E. Davis,** U. S. Department of Agriculture, Washington, D. C.

The Chemical Composition of Important American Soils, by **W. O. Robinson,** Department of Agriculture, Washington, D. C.

The Composition of the Loess Soils of the Transition Region, by **Frederick J. Alway,** University of Nebraska, Lincoln, Neb.

The Conservation of Phosphates in the Urine, by **Phillip E. Browning,** New Haven, Conn.

Section on Inorganic Chemistry.

One of the interesting and important papers presented at the opening session of the Section on Inorganic Chemistry was **A Plan for Organized Research and Analytical Chemistry in Successful Chemical Manufacturing,** by **William C. Ferguson,** of Laurel Hill, N. Y. Great stress was laid on the necessity of maintaining a research staff if an industry

is to grow and even keep pace with competitors, to say nothing of surpassing them. The author advises the establishment of two departments Research and Analytical with close working relations between the two.

The Research Department should investigate irregularities in current manufacturing, seek constantly to improve existing methods and carefully consider new methods of promise as they arise.

Great care should be exercised in selecting the staff for this department, for it is imperative that only the most fit be retained. Scientific education, inventive genius, imagination, keen observation and powers of correct deduction and the ability to discriminate between essentials and nonessentials must mark the man who is fit for the work of this department.

The organization of this department should include:

(1) Systematic abstracting from the principal foreign and American journals and patents of all subjects of interest to the corporation; copies of these abstracts should go weekly to all who can use them, with instructions to study them carefully and to immediately advise the department of any subjects that seem to warrant investigation.

(2) Thorough abstracting from the literature in the case of new work undertaken, thus becoming familiar with all that has been published relating to the subject. Repetition of the work of others is thus saved, valuable suggestions received and general knowledge of the subject enlarged.

(3) Systematic information should be constantly and promptly obtained of all records of imports and exports and duties on all finished products and raw materials that would interest the corporation in connection with its current business or as suggesting new articles of manufacture.

(4) Pamphlets describing machinery, structural material, etc., are many years in advance of books upon identical subjects. A pamphlet library should be maintained in co-operation with the engineering department.

All of the above work of translating, abstracting, etc., should be in charge of one competent man, with assistants if necessary.

(5) The superintendents should make monthly reports for the Research Department embodying all ideas of their own or their assistants that might in any way warrant investigation. There is no doubt that valuable suggestions would be made through such a system thoroughly carried out that might otherwise be lost, and also that the plan would stimulate closer thought and observation concerning all the details in manufacturing.

(6) Members of the Research staff should visit all possible outside manufacturing plants with the object of acquiring knowledge that could be applied by the corporation to its own process or organization.

(7) There should be, through proper connections, systematic, prompt advices of all improvements in European practice that would be of value to the corporation.

(8) Salesmen should seek to understand the different processes and the various ways in which the company's products are used and also know what substitutes are used for the company's products and such information should be reported to the Research Department by the Sales Department as deemed necessary.

(9) Certain research work might be undertaken by candidates for the degree of Ph.D. in universities, thus making these institutions take a cooperative part in developing practical questions.

The Analytical Department, under the chief analytical chemist, should control all work relating to sampling and analysis. Its duties should comprise:

The analysis and sampling of all raw materials and finished products as well as such analyses as are necessary in the intermediate steps of some processes in order to insure proper control. It should furnish figures used to calculate yields and perform all the analytical work in connection with investigations, which often involves the necessity of inventing new methods. It should do all analytical work that will aid the manufacturing, sales, purchasing and construction departments, and cooperate with the sales department in investigating complaints.

It should also pay strict attention to investigating and adopting better methods.

In order to estimate each man's capacity and to charge up the analytical work properly, the following system should be used: An analytical order should be made for each sample which comes to the laboratory and on the back of this order is recorded the amount of time spent by each chemist in making the analysis. When completed these orders should be filed under the various departments for which the work is done, and from them calculated a monthly statement of analytical charges, the material used being based upon the cost for the previous year. This system would make it a simple matter to note the progress of the analysis and the amount of work carried on by the different analysts.

Salaries of chemists in this department should be standardized as far as possible, and promotions made to the following positions according to kind of talent: Works Chemist, Assistant Superintendent, Research Department as Research Chemist, the Head Laboratory as Chief or First Assistant.

All men engaged should be informed of this system, hired on a month's trial, and only really promising men should be retained.

The following methods of advancing the efficiency of the department should be employed.

(1) Systematic visits to the different laboratories of the company by the Chief Analytical Chemist in order to see that the standard methods are being properly used and to pass on the general efficiency of all the company's laboratories.

(2) Occasional visits by the Chief Analytical Chemist to laboratories of other industries, in order to incorporate in the organization favorable developments made by others.

(3) Periodical meetings of the analytical chemists to promote cordial cooperation and to discuss specific subjects.

(4) The automatic exchange of chemists between the different laboratories to broaden the experience of the company's chemists.

(5) Monthly reports should be made by each laboratory of the company to the Chief Analytical Chemist, explaining all difficulties encountered in general work and also making suggestions for improvements in existing methods. This plan would make it possible for all the company's chemists to constantly and systematically cooperate and increase efficiency.

The Effect of "Lime-Sulphur Spray Manufacture" on the Eyesight.—By **James R. Withrow,** Ohio State University, Columbus, Ohio.—Attention is called to some manufacturing experiences with Lime-Sulphur Spray manufacture. Articles discussing lime-sulphur preparation from lime, sulphur and water, do not mention any discomforts arising. This was probably because of the small scale on which most of the work was done. The author found no trouble on a small scale. On the factory scale, however, the eyesight was temporarily and sometimes painfully effected, when thorough ventilation during boiling was not maintained. A polysulphide of hydrogen is suggested as the cause of the effect on the eyes. The remedy for the condition during manufacture was found to be hood-covered boiling tanks, and, besides this, ample ventilation at all times.

Meetings of Other Sections on Friday and Saturday.

In the **Section on Silicate Industries** the following five papers were presented on Friday:

In a paper entitled **"Notes on a Study of the Temperature Gradients of Setting Portland Cement,"** by **Allerton S. Cushman,** the Institute of Industrial Research, Washington, D. C., it is pointed out that the reactions which take place when hydraulic cements are tempered with water and while the mixture is hardening are as yet not understood. But since all chemical reactions are accompanied by definite and measurable thermal changes, complete temperature records of hardening cements must yield interesting and valuable data. The author describes a simple instrument for obtaining these records and gives a set of thirty-two temperature curves obtained with this instrument. In some cases the temperature gradients are much steeper and more sudden than in others. It is not possible at the present time to state what the ideal temperature gradient curve for a cement should be.

However, certain cements which did not stand the test and had been rejected, gave temperature curves which appear clearly abnormal to the eye, which indicates the value of a study of the temperature gradient as an additional method of control in cement testing.

A paper entitled **"The Control of Dust in Portland Cement Manufacture by the Cottrell Precipitation Processes,"** by **Walter A. Schmidt,** Los Angeles, Cal., describes a relatively recent application of the Cottrell dust precipitation process by electrostatic means, which has been repeatedly described in this journal. The Riverside Portland Cement Co., of Riverside, Cal., employs it with good success for controlling the dust in their rotary kiln gases.

The control of the dust arising from the rotary kilns in the manufacture of Portland cement is continually becoming a more serious problem. This is partly the result of the enormous growth of the Portland cement industry which now demands factories of such magnitude that the large volumes of gases leaving the stacks carry enormous quantities of dust into the atmosphere, but is probably more directly attributable to the present trend of public opinion, which continually demands a more thorough control of fumes and smokes.

The question of the proper relationships which should exist between the factory and the surrounding inhabitants has become a very important social problem. At the present time a large amount of hardship is being caused by improper action on one side or the other, often substantiated by our courts on the ground of mere technicalities. This is a problem which should receive the closest and most thorough study by a competent body in an endeavor to establish such laws as will draw a line of equity between the different parties coming into contact through the development of our modern industries.

Should every smelter, refinery and like industry emit poisonous and noxious fumes from its stacks and all other factories permit smokes and dusts to escape in unrestricted quantities, life in any large industrial center would be unbearable. On the other hand, however, most industrial furnace processes cannot be conducted without the production of large volumes of gases which usually carry from the furnaces volatilized materials and solid particles, these solids being swept along by the heavy rush of the gases.

As an average figure a rotary kiln 100 ft. long and 7 ft. in diameter, oil fired as on the Pacific Coast, has a volume of stack gases of 50,000 cu. ft. per minute; the gases above the combustion zone, in the stack, having a temperature of about 450 deg. Centigrade and carrying dust aggregating between 4 and 5 tons per day of 24 hours.

The principle of the Cottrell process, having been described in detail in this journal, need not be discussed here again. But some details of the plant at Riverside will be of interest.

The electrode system consists of two forms of electrodes; first, the discharge electrodes, which are made in various forms, depending upon conditions, but are always of a light construction and are so chosen as to maintain a heavy electrical discharge from them; secondly, the collecting electrodes upon which the solids are precipitated. These are usually of a heavy construction and the form and arrangement is so chosen that no discharge takes place from their surface. The two forms of electrodes are alternated across the apparatus with an electrode spacing of from 2 to 6 in., this distance varying with the conditions to be met. A series of these rows of electrodes is placed in the treater so that the dust particles are brought under the successive action of this series of electrodes. The length of the treater is so chosen as to affect the desired cleaning of the gases. The cross section of the apparatus is made such as to bring a balance between the two forces acting upon the suspended particles, namely, the frictional force tending to carry the solid particles along with the gases and the electrical force tending to draw the suspended particles out of the gas current.

In the installation at the Riverside Portland Cement Company the treater has a cross section of 12 x 16 ft. and an over-all length of 20 ft. The apparatus is placed upon a platform constructed at a height corresponding to the top of the original stacks, namely, 80 ft. above ground. Upon this platform is placed a short stack extension which extends through the roof of the building structure and is supplied with a damper of special design. Upon either side of the stack is placed a complete electrical treater separated from the stack extension by a large louvre damper. By means of these three dampers the gases can either be conducted through one or the other or both treating chambers or emitted directly into the atmosphere as occasion may warrant. Each stack is equipped with two treaters so as to have an auxiliary apparatus for each kiln. In case one treater should be shut down for repairs, cleaning or the like, the other treater will be able to take care of the gases with moderate efficiency. Under normal conditions the gases will be permitted to pass through both treaters, insuring a thorough cleaning of the gases. The electrode spacing is here chosen at 6 in. and there are twenty rows of discharge electrodes in series. The dust is precipitated upon the collecting electrodes, which are cleaned once every 3 or 4 hours by being given a mechanical rapping, this action being made automatic in so far that the operator merely puts an electric motor into operation. The dust falls into hopper bottoms from which it is again conducted into the bins feeding the rotary kilns. Each treater is supplied with a small outlet stack 20 ft. high which is sufficient to compensate for the resistance offered to the gases by the treater. As stated above, sensitive pyrometers do not indicate any change of temperature in the kilns or stacks when the gases are permitted to escape directly into the atmosphere or are passed through the treater.

The operating costs of the apparatus are low. A complete treater of the size described consumes approximately 7½ kw-hours. This includes electrical energy for all motors. A 5000-bbl. mill will, therefore, consume approximately 75 kw-hours in an entire installation. The manual labor required consists of one man per shift, of the character of men ordinarily employed to run electrical mill machinery. It is, however, usually advisable to have an extra man on duty. There is no deterioration in the apparatus under steady running and the machinery is subject to exactly the same wear as any other piece of electrical machinery.

One important question which has grown out of the present work at the Riverside Portland Cement Company lies in the possible utilization of the collected material as a source of potash for fertilizer purposes. This factory does not use clay in its raw mix but uses a decomposing feldspar which has a considerable potash content. In the burning of the cement the potash is volatilized and condenses again in passing up the stack. The greater part is caught in the electrical treater along with the dust which gives a dust-containing considerable potash value. Experiments have been conducted for some little time in the endeavor of utilizing this material either directly as a fertilizer "filler" or extracting the potash from the material with an aim of obtaining a concentrated potash salt. This work is not sufficiently far advanced to permit publishing definite figures.

A paper on **"Magnesia in Portland Cement,"** by **A. A. Klein** and **A. J. Phillips** of the Bureau of Standards, Pittsburgh, Pa., reaches the following conclusions:

The examination of a number of Portland cements showed that 7.5 per cent MgO may be present without being in the form of MgO or $MgO.Al_2O_3$.

MgO can form homogeneous compounds with CaO in the $\beta 2CaO_2SiO_2$ up to 6 per cent; beyond this a mixture of β orthosilicate and $CaO.MgO.SiO_2$ is formed.

MgO can form homogeneous compounds with CaO in the 3-1 aluminate up to 10 per cent; beyond this a mixture of 3-1 aluminate, $MgO.Al_2O_3$, and free CaO is present.

MgO acting as a flux assists in the formation of $\beta 2CaO.SiO_2$ and $3CaO.SiO_2$.

A paper on **"The Physical and Chemical Properties of Portland Cement,"** by **W. C. Reibling** and **F. D. Reyes,** Bureau of Science, Manila, P. I., gives an account of a very extended investigation. The main effort in this work was directed toward a study of those characteristics of Portland cement regarding which there exists the greatest amount of misconception and diversity of opinion, the object being to assist in the universal effort to formulate cement specifications so drawn as to guarantee the manufacture and use of Portland cement of the quality sought for.

"A brief summary of all the important conclusions arrived at can not be made, the interdependent nature of such conclusions preventing a brief statement of facts. However assuming that the quality in Portland cement which we need is constancy in volume and setting properties, and reliability in strength, and that it is of vital importance that this material both hardens rapidly and maintains a great strength, we believe that the enforcement of the following recommendations will increase the efficiency of the present standard cement specifications of the American Society for Testing Materials.

"A. Concerning the constancy of volume: (a) We can not hope to secure the desired efficiency in Portland cement unless the manufacturer is induced to burn his materials so that no seasoning is required to produce a sound cement. Therefore, it is necessary to demand perfect soundness in conjunction with a high specific gravity, and we recommend: (b) That failure to meet the requirements of the accelerated tests shall (in place of 'need not' as now specified) be sufficient cause for rejection.

"B. Concerning the specific gravity: (a) That the best burning and proper storing produces a product which has a high specific gravity (or a low loss by ignition). Therefore, (b) That the specific gravity of the cement as received (i.e., dried but not ignited) shall not be less than 3.10 unless the loss by ignition is less than 2.00 per cent. (c) That the above recommendation provides for the possibility of a well-burned cement with a lower specific gravity provided the low gravity is not due to subsequent absorption of volatile constituents; but our experience does not include such a possibility. (d) That the clause "Should the test of cement as received fall below this requirement a second test may be made upon a sample ignited at a low red heat" be omitted. (e) That the clause "A low specific gravity in conjunction with a high loss by ignition is positive proof of undesirable burning, adulteration or seasoning" be substituted for the present paragraphs concerning the significance of the specific gravity.

"C. Concerning the fineness: (a) As the specifications now stand, there is little incentive to induce the manufacturer to grind to the degree of pulverization that modern improvements in grinding machinery has made practicable unless his cement is so poor that extreme fineness is necessary to enable it to pass the requirements for strength and soundness. Therefore, (b) That the cement shall leave a residue of not more than 5.00 per cent by weight on the No. 100, and not more than 20 per cent on the No. 200 sieve.

"D. Concerning the tensile strength: (a) That the average of at least four briquettes representing at least two separate mixtures of the same sample shall be taken for each test, excluding any results which are manifestly faulty.

"E. Concerning retests: (a) Manufacturers should be impressed with the fact that these are minimum requirements; that ample provision already has been made in the specifications for lack of uniformity in testing as well as in real quality; and that we demand a quality so superior that, regardless of the variable factors, the ability of the cement to pass all requirements shall be a certainty. Therefore, (b) That the results obtained from the original test shall be considered as final unless it becomes evident that a serious error in sampling or testing has resulted in totally misrepresenting the quality of the cement. In other words, that "border-line" cements should be avoided as much as possible.

"F. Concerning the practical significance of the above recommendations: (a) Manufacturing conditions are such that we can not hope to secure Portland cement which contains no free lime. Also, it is realized that the proposed specifications are not perfect. However, we believe that the enforcement of the above recommendations will support and promote the best practice in grinding and burning, and accordingly, secure greater uniformity and efficiency than the present specifications: (b) Without the hearty, honest cooperation of both manufacturer and user little can be accomplished. The degree of fineness and burning are important financial considerations to the manufacturer, and the consumer should buy on a basis of quality. (c) The testing of a great number of commercial Portland cements from many parts of the world has convinced us of the feasibility of these recommendations from both an economic and practical standpoint, and the results obtained have repudiated all claims to the contrary. For instance, a certain manufacturer in America stated that owing to a long sea voyage he could not guarantee his cement to pass the 3.10 requirement for specific gravity. Our work showed conclusively that cement stored in good barrels undergoes very little change due to atmospheric influences and many cements imported from Europe and America show consistently a gravity above 3.10 and a low loss by ignition. There are cements which as stated in the "Introduction" of our work show the most remarkable uniformity in physical properties.

"We desire to emphasize the importance of the calcium hydroxide-phenol microscopic test for free lime, as in every instance the physical and chemical properties of the different products examined demonstrated the accuracy and usefulness of this test. As stated, we believe that in the hands of an expert it gives more definite and reliable information regarding the constancy of strength and volume

than the usual 28-day or even 3 or 6-month tests. However, there is one undesirable feature to this test; namely, that it requires considerable experience and ability correctly to interpret the significance of the phenolate crystals formed on the microscopic slide. Therefore, in order to make this test generally practicable and universally dependable it must be simplified or made quantitative. Certainly, its possibilities and importance warrant much more extended research in this drection than we have had opportunity to accomplish."

A paper on **"The Use of the Higher Phenols in Testing for Free Lime in Portland Cement,"** by **David C. McFarland** and **Harry F. Hadley** of the University of Illinois, Urbana, Ill., reaches the following conclusions:

That calcium phenolate and the calcium salts of homologues of phenol are very difficultly soluble in any of the common solvents.

That phenol and its homologues do not at all act with the same rapidity, or to the same degree of completeness with free lime. P-cresol apparently reacts immediately; b-naphthol and phenol do not react so rapidly and the remaining homologues, which were tried, react only slightly.

That a roughly quantitative extraction of free lime is possible by means of a properly proportioned mixture of para cresol, with absolute alcohol, and a trace of water, when the total quantity of lime is small. The method does not give good results with large quantities of free lime.

That p-cresol with alcohol and a trace of water gives a more rapid test for free lime than White's test. Also the test is more delicate for it will give an abundance of crystals where White's test gave only a few. Apparently the test is too delicate for practical use.

That the aging of cement for a period of time does not necessarily destroy all the free lime which it contains.

Friday and Saturday Sessions of Section on Photochemistry.

The first session of this section was devoted to a symposium on the practice of photography, the following papers being read:

Preliminary Studies on Direct Photographic Positives.—A paper by **G. A. Perley** and **Alan Leighton,** New Hampshire College, Durham, N. H., announcing the following results:

(1) By exposing a plate in a camera to an object illuminated by a Cooper Hewitt mercury arc light at a given distance, a positive was obtained after five minutes' development in the following solution maintained at 12° C.: 0.0030 grams thiocarbamide, 0.0378 grams hydroquinone, 0.2837 grams Na_2SO_3, 0.0567 grams Na_2CO_3 and 12.7627 grams water per square inch of plate surface.

(2) The temperature during development must be carefully regulated. Utilizing a given concentration, the temperature cannot be varied more than one degree centigrade.

(3) The quantity of the developer utilized governs the resultant positive. It is best expressed in plate surface units.

(4) An excess of any constituent which favors an increase in the development of the latent image yields a partial negative (or a masked positive). An insufficient amount produces uniform development and a resultant fog.

(5) An excess of thiocarbamide acts as a solvent for the emulsion. An insufficiency does not visibly affect the thin negative resulting from normal development.

(6) No single constituent can be omitted from the above developer to obtain good results.

(7) At 12° C. a small quantity of water (high concentration) causes the thiocarbamide to exert its solvent action. A large quantity of water (low concentration) retards the development of the latent image with the production of a fog.

(8) Under the same conditions as in (1) at 18° C. an exceedingly good positive can be obtained on a lantern slide plate with 0.0030 grams thiocarbamide, 0.0387 grams hydroquinone, 0.2907 grams Na_2SO_3, 0.075 grams Na_2CO_3 and 7.8461 grams water per square inch of plate surface.

(9) The only source of dissatisfaction with the present positive is: First, the bluish color of the deposit; secondly, the necessity of a preliminary appearance of a thin negative; thirdly, the appearance by reflected light of a yellowish fog.

The Direct Production of Positives in the Camera by Means of Thiourea and Its Compounds, a paper by **Francis C. Frary, Ralph W. Mitchell** and **Russell E. Baker,** University of Minnesota, Minneapolis, Minn., giving the following summary:

The conditions for successfully carrying out the Waterhouse process of producing positives have been carefully studied and are given in detail. The most important of these is the temperature of the developer.

The double salts formed by thiourea with ammonium bromide and chloride work better than the thiourea itself. The amount of restrainer used varies with the salt used.

The character of the developing agent and the quantity of alkali in the developer play an important part in the process; a strongly alkaline hydrochinon developer is recommended and the thiourea solution should be mixed with this as needed for use.

The process gives positives of excellent detail, with about the gradation and density of a first-class negative. The exposure is relatively short, being about double that required for the production of a normal negative.

The afternoon meeting was a joint session with Sections IVa and Ve at the Camera Club, 121 West Sixty-eighth Street. Here there was an exhibition of photographs and afternoon tea was served. Two papers were read, as follows:

The Permanency of Paintings, by **Wilder D. Bancroft,** Cornell University, Ithaca, N. Y., discussing the effect of the absorption of light on pigments and giving the following general results:

1. Light may change pigments in all sorts of ways, but the change in color is usually due to an oxidation.

2. A drier in the oil may cause reduction of a pigment, the oils being oxidized; or it may accelerate the oxidation of the pigment.

3. Lead sulphide is oxidized to sulphate by light, and pictures which have blackened in the air can, therefore, be improved by an exposure to bright sunlight.

4. Colors which are really permanent may seem fugitive if prepared improperly or if ground in oil that has been bleached with acid.

5. Madder probably protects vermilion by cutting off the rays which are most active in producing the allotropic change.

6. Varnishes keep out moisture, air and ultra-violet light.

7. Pigments produced by oxidation are more likely to be stable than those produced by reduction.

8. By changing the nature of the precipitating agent it ought to be possible to vary the fastness of lakes to light.

9. From the analogy with dyeing, it seems probable that the maximum fastness to light can be obtained when lakes are made with a suitable mixture of precipitating agents.

10. It is doubtful whether copper salts increase the fastness of all dyes to light.

11. Rapid tests for fastness to light can be made with solutions of peroxides or of persulphates.

12. The relation between the stability of vermilion, etc., and the methods of preparation is a problem in colloid chemistry

Rapid Testing of Dyes and Pigments, a paper by **Wilder D. Bancroft, Arthur S. Elsenbast** and **George E. Grant,** Cornell University, Ithaca, N. Y., giving the results of experiments made to determine the effect of light on dyes and pigments. Since most colors are bleached by oxidation, it seemed that it ought to be possible to prepare solutions of oxidizing agents of varying strengths such that one could say that a given dye or pigment was practically fast to light in case it did not bleach perceptibly in a given solution within a given time. Our experiments are only preliminary ones, but they indicate the possibility of working out a satisfactory method along these lines.

The general results of this paper are:

1. Methylene blue, methyl violet, Victoria green, magenta, azo red and eosine are bleached at ordinary temperature by a suitable concentration of hydrogen peroxide. It is easy to arrange the experiment so as to bring out marked differences in the relative stability of these dyes.

2. Methylene blue and azo red fade gradually; methyl violet and eosine fade slowly at first and then quite rapidly; magenta and Victoria green fade fast at first and then gradually.

3. Taking practically complete bleaching as the endpoint, the order of stability is methylene blue, azo red, methyl violet, eosine, Victoria green and magenta, the last being the most fugitive. For shorter intervals of time the order may be methylene blue, methyl violet, eosine, azo red, Victoria green and magenta.

4. A similar bleaching effect can be obtained with persulphate solutions.

5. Solutions of all six dyes bleach in the sunlight and also in the light of the quartz, mercury vapor, lamp. The order of stability is not the same as in the oxidizing solutions, being Victoria green, magenta and azo red, methyl violet, methylene blue and eosine, the last being the most fugitive. This discrepancy is due in part to the fact that the oxidation of the dyes is not always due to light of the same wavelength.

6. We have studied the action of hydrogen peroxide and of sunlight on the following lake colors: eosine vermillion, scarlet lake, Ian red, red lake, eosine lake, magenta lake, blue mauve, green lake deep, green lake yellowish.

7. All the lakes, except the greens, bled badly and all were bleached very much by hydrogen peroxide. They are very much more stable to hydrogen peroxide and to sunlight than the corresponding dyes.

8. The dry lakes were not much affected by six weeks' exposure to occasional sunlightt, the eosine fading much the most.

9. When suspended in water, the lakes are bleached by sunlight, the order of permanency under the conditions of the experiment being Ian red, the greens, red lake, magenta lake and blue mauve, scarlet lake, eosine vermilion and eosine lake, the last being the most fugitive.

10. These preliminary results indicate the possibility of working out rapid qualitative tests as to the stability of dyes and pigments in sunlight. Such tests are absolutely necessary for any systematic study of the factors affecting stability.

Entertainments on Thursday and Friday.

On the evening of Thursday, September 5th, the American Institute of Chemical Engineers held a banquet at the Chemists' Club.

The program of entertainments for Friday evening, September 6th, contained two noteworthy features. One was a "kommers" to the Section on Pharmaceutical Chemistry, tendered by the Apotheker Verein of New York City.

The other was a reception to the Japanese delegates to the congress, tendered by Dr. and Mrs. Takamine.

Section on Fuels and Asphalt.

At the Friday session of the Section of Fuels and Asphalt the following six papers were presented:

Oil Inspection.—A paper on "uniform oil inspection from a legal point of view," by **C. D. Chamberlain** of Cleveland, Ohio, deals with the subject under the following headings: Definitions, uses, and characteristics of petroleum, basis of inspection laws, present condition.

A paper on **A Comparison of the Engler and Saybolt Viscosities of Mixed Oils,** by **T. T. Gray,** of the Tide Water Oil Company, Bayonne, N. J., gives the results of comparative tests made with the Engler-Saybolt instruments. The ratios of the readings of the two instruments are given in diagrams which, however, permit a ready conversion from Engler specific viscosities to Saybolt viscosities and vice versa.

Petroleum Tester.—A paper in German by **Geheimer Begierungsrat,** Prof. Dr. **H. F. Wiebe,** of the Reichsanstalt, refers to the fact that at the Vienna Petroleum Congress it was decided to use generally the Abel-Pensky petroleum tester for dectermining the inflammation points of petroleum. The question is to what other temperature limit this instrument can be used. According to the German regulations it may be used up to 50° C., and for higher temperatures the Pensky tester is used instead. The investigations of the present author show, however, that the Abel apparatus, in a modification, which is described, may be used without hesitancy up to temperatures of at least 104° C.

A brief paper on **New Researches on the Lubricating Oils,** by Prof. **A. M. Nastukoff,** Moscow, Russia. A continuation of his researches on the condensation of the naphtha distillates with formalin in presence of less sulphuric acid than is necessary for obtaining ordinary solid and insoluble formolit.

Asphaltum.—A paper in German by **R. Zaloziecki** und **C. Zielinski,** of Lemberg, Galicia, discusses the formation of asphaltum from earth alloys.

Fuels in the Navy.—In a paper on "the use of fuels in the United States Navy" by **H. I. Cone,** U. S. N., Washington, D. C., the author discussed the various applications to which coal, fuel oil, and gasoline are put in the navy.

Section on Coal Tar Colors and Dyestuffs.

After the organization of the Section and the transaction of business the regular program was taken up as printed in the program.

The Development of Hydrosulphites in Their Relation to Modern Dyestuffs.—A paper by **Philip S. Clarkson,** of New York, N. Y.

In 1869 when Schuetzenberger first made sodium hydrosulphite and in 1872 when he, together with Lalande, applied it to the preparation of indigo-white and introduced a vat for indigo dyeing based on its use, a basic foundation was laid for the practical application to the fiber of the latest and the most desirable group of synthetic dyestuffs. By the proper selection of dyestuffs the printer can furnish shades which can be guaranteed as fast to light, washing, wearing and other injurious influences; in fact, almost that the color will last longer than the fiber. This condition has undoubtedly been brought about by the discovery and perfection of the hydrosulphite-formaldehyde compounds.

This was followed by an address by **L. Da Costa Ward** on the need of establishing official tests in dyeing and textile chemistry.

Joint Meeting of Sections on Photochemistry, Coal Tar Colors and Paints.

The afternoon session was a joint meeting with Sections IX and Ve at the Camera Club where there was an exhibition of photographs.

During the afternoon **Wilder D. Bancroft** spoke on the **Permanency of Paintings.** A paper on the **Rapid Testing of Dyes and Pigments** also was presented by one of the authors, **W. D. Bancroft, A. S. Elsenbast** and **G. E. Grant.** Other reference to these papers appears under Section on Photochemistry.

Section on India Rubber and Other Plastics.

The program of this section for Friday contained two papers. One, by **M. B. Setlik** and **J. Zofka,** in French, related to analyses and tests of rubber goods.

The second paper described **A Direct Determination of Rubber Applicable to Specifications on Vulcanized Rubber Goods,** the author being **C. R. Boggs,** of Boston, Mass.

The method is a modification of the tetrabromide method for raw rubber and is essentially a modified Budde method.

Section on Biochemistry Including Pharmacology.

The program of the section devoted to Biochemistry, Including Pharmacology, was carried out practically as announced. The following papers were presented either by the authors or read by titles:

Fatty Acid Esters of Glucose.—A paper by **W. R. Bloor** of the Laboratories of Biological Chemistry of Washington University, St. Louis, Mo., describing the preparation and properties of these substances and giving results of feeding and injecting the same into animals.

La Importanza Fisiologica del Manganese nell' Organismo Animale.—By **Guido M. Piccinini,** University of Bologna, Bologna, Italy.

Sur la Résistance de la Peroxydase a l'Amoniaque et sur Son Activation par Contact avec l'Alcali.—By **J. Wolff,** Paris.

Sur les Elements Mineraux Conténus dans la Caseine du Laît.—By **M. L. Lindet** of Paris.

La Question de l'Acide Sulfureux dans les Vins Blancs.—By **Philippe Malvezin,** Professeur aux Laboratoires Bourbouze, Paris, France.

The Iodine Content of the Small, Medium and Large Thyroid Glands of Sheep, Beef and Hogs.—A paper by **T. B. Aldrich** of the Research Laboratory of Parke, Davis & Co., Detroit, Mich., giving results of investigations of the thyroid glands of sheep, beef and hogs. The author concludes that the employment of either hogs or beef thyroid is more rational than the employment of sheep glands.

Section on Bromatology.

The opening session of the section devoted to Bromatology was held Friday morning, September 6. On account of the absence of many of the members who were on the program their papers were merely announced by title.

The Chemical Changes Taking Place in Milk Under Pathological Conditions.—A paper by **Lewis W. Fetzer,** of the Department of Agriculture, Washington, D. C.

Food Standards: Their Nature, History and Functions.—The author, **William Frear,** of State College, Pennsylvania, gives a general discussion of food standards, considering the subject under the heads of nature, matter, consistency, form and function of such standards.

On the Chemical Composition of "Sake."—A paper by **T. Takahashi** and **Goro Abe,** College of Agriculture, Tokyo, Japan, giving the results of various investigators and a table of substances obtained from Sake.

Interpretation of the Results of Wine Analysis.—The author, **Charles S. Ash,** of San Francisco, Cal., discusses the difficulty of interpreting wine analyses without working a hardship on producers. He devotes space to the consideration of artificial wines and adulterations and alterations of wine products.

Contribution to the Chemistry of the Ripening of "Shiokara."—A paper by **Y. Okuda,** College of Agriculture, Tokyo, Japan, discussing the autolysis and action of the microbes used in preparing this food material, and giving results of attempts to isolate the enzymes which play an important part in the process.

Quantitative Determination of Creatine, Creatinine and Monoamino Acids in Some Fishes, Mollusca and Crustacea.—A paper by **Y. Okuda,** Tokyo, Japan, giving results of experimental work, in which he finds that creatine occurs in fish, but not in mollusca or crustacea. Creatinine occurs in smaller quantities. Most of the proteins are soluble in 10 per cent Na Cl solution, which fact must be considered in preserving fish.

A Study of the Composition of Cider Vinegar Made by the Generator Process.—A paper by **L. M. Tolman** and **E. H. Goodnow,** Bureau of Chemistry, Washington, D. C., giving the results of factory experiments on a very large scale of the conversion of fermented cider into vinegar in the ordinary generator. Results show that vinegars made by this process are practically as uniform in composition as the cider from which they were made.

Section on Analytical Chemistry.

At the Saturday morning session of this section the following program was presented:

Reception of the Report of the International Committee on Analyses, L. Lindet, President.

The following reports of sub-committees were announced:

Dosage des elements rares dans les minerais et des aciers. G. Chesneau.

Controle de la purite des reactifs. T. S. Fresenius.

Methodes Uniformes pour le prelevement des echantillons. H. W. Wiley.

Methodes Uniformes pour la representation des resultats des analyses. H. Fresnius.

Analyse des vernis gras. G. Halphen.

Dosage de l'eau dans les minerais et les combustibles. Geo. T. Holloway.

Analyse des matieres colorantes artificielles. Fred. Reverdin.

Estimation du degre de blutage des farines. V. Villavecchia.

Section on Inorganic Chemistry.

The program for Saturday, September 7, was carried out in a joint meeting with the section on silicate industries. Some of the papers are more fully presented under that section.

Section on Explosives.

The following is the program for the Saturday session of this section:

Misuse of Explosives. Thomas M. Chatard.

The Transportation of Dangerous Goods by Water. Jules Abey.

Section on Organic Chemistry.

The program for Saturday morning, September 7, was as follows:

The Possibility of Reducing the Cost of Malic Acid. W. H. Warren and M. R. Grose.

Isomeric Naphthenic Acids. F. W. Bushong.

The Action of Potassium Xanthogenate on Halogen Malonic Acids. E. Biilmann and E. H. Madsen.

Parabrombenzoylacetic Ester. W. J. Hale and L. Thorp.

Ueber Chinoncarbonsaeureester. K. Brunner.

On Some Derivatives of 4-Hydroxyisophthalic Acid. F. D. Dodge.

Studies in Esterification. V. The Esterification of Amides and Thioamides and the Formation of Dithia Esters. E. E. Reid.

Section on Industry and Chemistry of Sugar.

The following is the program arranged for this section Saturday morning, September 7

L' emploi de la cellulose (pate a papier) comme produit filtrant dans l' industrie sucriere et autres. Auguste Aulard.

La dessication des produits vegetaux s' impose-t-elle. Aguste Aulard.

Fabrication d' une farine sucree de betterave (beet meal) son emploi dans l' alimentation humaine et animale. Aguste Aulard.

Bestimmung des Reinheits-Quotientin des Rubensaftes in der Difestionslosung. Franz Herles.

Objectionable Nitrogenous Constituents in Sugar Cane Juice. Fritz Zerban.

Section on India Rubber and Other Plastics.

The program for the Saturday morning session of this section was as follows:

On the Relationship Between the Amount of Resins and the Viscosity of Rubber Solutions. J. G. Fol.

The Action of the Resins in the Vulcanizing of Rubber. Lothat E. Weber.

On Some Preliminary Observations Regarding the Causes of Natural Change in the Latex of Heavea Brasiliensis; and on the Depolymerization of Caoutchouc and its Conversion. G. Stafford Whitney.

Section on Paints, Drying Oils and Varnishes.

The following program was arranged for this session, Saturday morning, September 7:

The Struggle between White Pigments in Europe. Gaston de Pierres.

The Technology of Varnish Manufactures with Notes on an Improved Scientific Process. J. Cruickshank Smith and Gaston de Pierres.

Modern Painting Methods in the Navy. Henry Williams.

Carbon Black and Lamp Black. Godfrey L. Cabot.

Section of Starch, Cellulose and Paper.

At the Saturday morning session of this section the following program was provided:

Consumption of Caustic Soda by Various Woods and Under Varying Conditions of Cooking, Including the Influence of This Consumption on the Yield and Bleaching of the Fibres Produced. E. Sutermeister.

The Influence of Temperature on Hydration and Absorption of Alkali by Regenerated Cellulose. Clayton Beadle and Henry P. Stevens.

The Influence of By-Products on the Development of the Industry of Corn Products. H. C. Humphrey.

Section of Fermentation.

The following is the program for the Saturday morning session of this section, the papers being presented either in full or by abstract.

Influence de la pression sur la fermentation alcoolique. Lindet et Ammann.

Application of Taka-Koji in Distilleries. Nils C. Ortved.

The United States Standard for Malt Vinegar from the Fermentation Standpoint. Francis Wyatt and Schlichting.

Determination de la valeur des masses filtrantes pour la filtration de la bierre. A. Fernbach and J. Crolbois.

Materials used in the Manufacture of Filtermass. C. A. Nowak.

On Bacillus Natto. A Sawamura.

On the Budding Fungi of Shoyu-moromi. T. Takahashi and M. Yukawa.

On Symbiotic Life of Yeast Races. A. J. J. Vandevelde.

Section on Agricultural Chemistry.

The Saturday morning session of this section was held jointly with the section of silicate industries under which the papers are more fully presented.

Section on Pharmaceutical Chemistry.

There was but one paper presented at the Saturday morning session of this section, on **The Influence of Heat and Chemicals on the Starch Grain. Henry Kraemer.**

Experiments in Feeding Guinea Pigs "Salts of Tin" in Measured Quantities for Several Weeks.—A paper by **H. A. Baker,** of New York City, gives the following conclusions: that daily doses of 12.6 mg. of tin are fatal in from 9 to 25 days; that there is a progressive accumulation of the tin in the liver, and that this accumulation is eliminated slowly after feeding is discontinued.

Special Adaptation of Iodine Titration Methods for the Estimation of Tin, Especially in Connection with Determination of "Salts of Tin" in Canned Foods.—A paper by **H. A. Baker,** of New York City, describing a new method, which is an adaptation of parts of several well-known methods.

The author claims advantages in rapidity and accuracy, and the absence of complications.

"Springers" in Canned Foods: Causes and Prevention.—The author, **H. A. Baker,** of New York City, discusses the causes of swelling or bulging of canned foods, and gives directions for avoiding this phenomenon. The filled cans must have uniform head space, adequately exhausted. After sealing, the cans must be processed as soon as possible. Highly acid foods should be kept in enamel-lined containers.

The Relation of the Chemist to the Wine Industry.—A paper by **Charles S. Ash,** of San Francisco, Cal., states that there are few, if any, industries in which it is so difficult for the chemist to prove his necessity as in the manufacture of wine, because it is not a true manufacturing industry. In spite of temporary discouragements, however, the wine chemist is having more intimate relations with the wine industry and hopes to become permanently established.

Proposed Method for the Estimation of Tin in Canned Foods.—A paper by **H. L. Lourie,** of the United States Appraiser's Stores, New York City, describing a method evolved to insure accuracy and rapidity. Directions are given for use of the method for such substances as fish and syrup.

Section on Photochemistry.

The program for the Saturday morning session of this section was as follows:

Action desorganisante des divers alcalis ou de leurs succedanes sur les couches gelatinees des plaques et des papiers photographiques, en vue de leur emploi dans les revelateurs. A. L. Lumiere and A. Seyewetz.

The Microstructure of Wet-Plate Negatives. F. C. Frary and G. H. Woolett.

Sur l' emploi des sels de mercure pour le developpement physique et notamment pour le developpement apres fixage. A. L. Lumiere and A. Seyewetz.

Some Observations on the Permanency of Gold-toned Silver Prints. L. H. Baekeland.

The Second Positive. W. D. Bancroft, A. S. Elsenbast and G. E. Grant.

Section of Law and Legislation Affecting Chemical Industry.

The program for this section for Friday and Saturday was as follows

The Expert Witness. Edward J. McDermott.

Misuse of Explosives. Thomas M. Chatard.

The Transportation of Dangerous Goods by Water. Jules Aebey.

Section on Physical Chemistry.

The program of the Friday and Saturday sessions of the Section of Physical Chemistry was as follows. Abstracts of several of these papers will be given in one of our next issues:

The Vapor Pressure of Some Zinc Chloride Solutions. A. W. C. Menzies and Henrik Boving.

The Ternary System: Caoutchouc, Benzol and Water. W. P. A. Jonker.

(1) Equilibrium in System of Sulphuric Acid, Lithium and Ammonium Sulphates.

(2) Equilibrium in the System of Sulphuric Acid, Ammonium and Lithium Sulphates and Water.

(3) Some Absorption Curves of Commercial Tanning Materials with Cotton. G. C. A. Van Dorp.

Solubility in Cases of Altered Solid Phases. Arthur Rindell.

Ueber die Reaktion zwischen Ozon und Wassertoffperoxyd. Victor Rothmung.

The System Oxalic, Oxalate of Ammonium and Water at 30 and 45. H. W. Woudstra.

On Mixed Crystals of Potassium and Ammonium Chlorides. K. Uyeda.

Equilibria in Systems Containing Alcohols, Salts and Water, Including a New Method of Alcohol Analysis. Geo. B. Frankforter and Francis C. Frary.

Some Considerations on the Chemical Kinetics of Enzymes. K. Ikeda.

The Chemical Properties and Relative Activities of the Radio Products of Thorium. Herbert N. McCoy and Charles H. Viol.

Sur les theories et les formules de la chimie physique. M. Albert Colson.

On the Polymerization of Liquids and a General Method for Determining Its Relative Value. M. M. Garver.

Concerning the Significance of the Quantity b in the Equation of van der Walls. T. W. Richards.

Chemical Kinetics of Catalase. E. Yamasaki.

Binary Mixtures of Ethyl Ether and Chloroform. Charles Baskerville and Marks Neidle.

Section on Fermentation.

The Friday session of this section comprised an interesting program of the following papers:

Sugar and Acid Content of American Native Grapes. Wm. B. Alwood.

Sulphurous Acid in Wine Making. Frederick T. Bioletti.

Les vins blanc de la Moselle et du Rhin. P. Carles.

La sterilisation des vins. G. Hinard.

The Viticultural Industry of California and the Manufacture of Its Wines. P. C. Rossi.

Some Characteristics of American Wines. Lee J. Vance.

Modern Methods of Brewery Refrigeration. A. G. Koenig.

The Analysis of Hops as Basis for Their Valuation. Alfred Fischer.

Does the Hard Resin of Hop Impede the Solvency of the Soft Resin in Petrolic Ether and Beer wort? E. H. Naatz.

Oxidation of Atmospheric Nitrogen and the Development of the Resulting Industries of Norway.

Public Address by the Representative of Norway.

Undoubtedly one of the most interesting features of the whole Congress was the address by **Dr. Samuel Eyde,** who is not only one of the joint inventors of the Birkeland-Eyde process, but who has been able to promote the industry of the fixation of atmospheric nitrogen within ten years in such a way that it is now the biggest and most marvelous new industry of Norway. After explaining that the atmosphere surrounding us is composed of oxygen and nitrogen and that the task of the new industry is to create by the union of the oxygen and nitrogen gases new chemical combinations which can be utilized in the world's household, he referred to the pioneer work of Priestley and Cavendish, of Sir William Crookes and Lord Rayleigh, and of Bradley and Lovejoy at Niagara Falls.

The Conquest of the Air by the Chemist

The difference between these previous methods and those of the Birkeland-Eyde process is that the latter employ large quantities of electric energy in the electric arc and have first found out the best method of doing this, while it was previously believed that it was small quantities of energy that gave relatively the best results.

Dr. Eyde described the principle of the Birkeland-Eyde process which has been discussed in full in our Vol. II, p. 399; Vol. IV, pp. 126, 295, 360; Vol. VII, p. 304 (compare also Vol. IX, pp. 436, 485, 545). The principle of the Birkeland-Eyde system is to drive the air through a flame disk produced by electromagnetic deviations of an electric arc.

With the commercial furnace which they have developed they have been able to reduce the whole operation to such a routine practice that the furnace burns for weeks without any regulation worth mentioning. The maintenance of the furnace and its repairs are simple, as the most exposed portions, the electrodes, only require to be changed every third or fourth week, and then only a small part of them, and the fireproof masonry every fourth to sixth month.

Details of Commercial Furnace

The temperature of their flames exceeds 2500° or 3000° C. The temperature of the escaping gases may vary between 800° and 1000° during ordinary working. The furnaces are made of cast steel and iron, the middle of the furnace being built out to a circular flame chamber. The electrodes are led radially into this flame chamber. By aid of centrifugal fans the air is brought into each furnace through tubes from the basement.

The experimental work of Birkeland and Eyde started with a furnace not larger than could be held in a hand, and now they have succeeded in building furnaces which consume more than 5000 hp and from absorption apparatus on a laboratory scale with a few liters capacity they have passed over now to absorption towers of granite with a capacity of 600 cubic meters or 600,000 liters each.

Dr. Eyde then discussed the Schoenherr furnace which has been described in detail, for instance, in our Vol. VII, p. 245. In the Schoenherr furnace the air passes in a spiral path around a very long drawn-out arc upwards, the furnace being of a long tube form. Dr. Eyde remarked that the reaction in the Schoenherr furnace is identical with that obtained in the Birkeland-Eyde furnace and the yield as far as the results now obtained shows practically the same.

Dr. Eyde stated that at Notodden they have only furnaces of the Birkeland-Eyde system from 1000 kw to 3000 kw. At Rjukan there are, however, furnaces of the Birkeland-Eyde system of 3000 kw as well as furnaces of Schoenherr's system all of 1000 kw.

The operation aside from the electric furnace was described by Dr. Eyde as follows: The air for the furnaces is procured by swiftly revolving ventilators. The air is conducted through large iron pipe lines to the furnaces. When the air in the flame chamber has been treated by the electric flames, the nitrous gases formed pass out through a channel to two fireproof lined gas-collecting pipes, which convey the gas through the basement to the steam boilers in which the temperature is reduced from 1000° C.

Mechanical Engineering Details

The steam produced in the boilers is utilized in the further treatment of the products. In the boiler house there are also two large and two small air compressors, which supply compressed air for pumping acids and lye in the factory's various chemical departments.

The gases pass on from the steam boilers through an iron pipe into the cooling house, with the object of completing the cooling commenced in the steam boilers. This cooling is necessary in order to obtain a suitable absorption. Each cooler consists of a great number of aluminium tubes, over which cold water runs, while the hot gases pass through them. The temperature of the gas is considerably reduced. From the cooling chambers the gases go on to the oxidation tanks.

Cooling House and Oxidation Tanks

These oxidation tanks are vertical iron cylinders, lined with acid-proof stone. The object is to give the cooled gases a sufficient period of repose in which the oxidation of the oxide of nitrogen may have time to take place. The necessary amount of oxygen is present in ample quantity in the air which accompanies the gases from the furnaces. From the oxidation tanks the gases are forced by blast engines into the absorption towers.

All the towers are filled with broken quartz, which is neither affected by nitrous gases nor by nitric acid. To assist the passage of the gases on their way from the furnaces there are centrifugal fans, constructed of aluminium on each row of towers.

Absorption Towers

The gases enter at the basis of the first tower, go up through the quartz packing and thence by a large earthenware pipe enter the top of another tower through which they pass downward through the quartz to the bottom of the third tower, and so on, until the air, relieved of all nitrous gases, leaves the last tower. Water trickles through the granite towers and this is gradually converted into a weak nitric acid, while the liquid used in the iron towers is a solution of soda.

The absorbing liquid enters the top of the tower and is distributed in jets by a series of earthenware pipes, so that the permeating gases come in immediate contact with the absorbing liquid. In the granite towers nitric acid is thus formed and in the iron towers a solution of nitrate of soda.

The liquid emerges in a constant even stream from the bottom of the towers, that from the granite towers running into a granite cistern. Hence it flows into the montejus which serve to pump up the acid, which has to pass repeatedly through the tower before it has become strong enough for the purpose for which it is intended. The montejus are of stoneware strengthened with iron shields, are worked by compressed air and send the acid up into large stoneware jars. From these jars the acid again runs through the towers as described. The montejus work automatically.

The iron towers are percolated, as already mentioned, by a solution of soda, otherwise the whole process is practically similar to that in the granite towers. The solution of soda, owing to its far greater power of absorption, effects the separation of the last remains of nitrogenous gases from the accompanying air. Of the entire quantity of nitrous gases passed through the absorption system about 97 per cent is absorbed.

The finished nitric acid coming from the towers, which has a strength of about 30 per cent by volume, is collected in granite cisterns, from which it is drawn to what is called the solution works. These consist of granite vats filled with limestone over which the acid is poured. This drives off, with violent effervescence, the carbonic acid contained in the limestone, while the nitric acid takes its place and forms a watery solution of nitrate of lime or calcium nitrate.

Solution Works

The rest of the acid is neutralized in small towers filled with milk of lime and is now pumped into vacuum evaporating apparatus. The object in boiling in vacuum is the well-known fact that great saving is thereby effected in the heat required.

The steam required for the evaporization is obtained from the steam boilers, heated, as before mentioned, by furnace gases. The concentration of the nitrate solution in the evaporizing plant is continued until the specific weight of the liquid at a given temperature shows a content of 13 per cent of nitrogen.

This solution is then sufficiently evaporated and can be pumped up into the solidification chambers, where it is conducted upon a revolving cylinder, cooled on the inside, where it stiffens so quickly that it easily can be brought to spring off into small leaf-similar pieces, which without difficulty can be granulated in the crushing mill, where the mass is reduced to a granular state.

The coarse powder so produced is raised by elevator to a vat, from the bottom of which it is tapped into casks holding 100 kilograms net weight. The gas led into the iron tower forms with the solution of caustic soda a solution of nearly pure sodium nitrate. This is concentrated by evaporation in the same sort of apparatus as above and allowed to crystallize. The crystals are dried in a certrifuge and tapped into casks. The barrels are made at the factory's own cooper's shop and are lined with paper to guard against damp. Besides these two products, nitrate of lime and nitrate of soda, they have during the last year at the Notodden Works taken up the manufacture of nitrate of ammonia, which product already has won a good reputation, and in comparatively large quantities is shipped to the United States.

In this industry the water power is all important. The works now being built are all situated in the southeastern part of Norway and the Telemark River. The first work, the Notodden nitrate factories are admirably situated at the lake of Hiterdal, about 50 feet above the level. A short channel with a series of locks permits communication with the town Skien, an important seaport at the head of the fjord. Under the present conditions vessels of 200 tons burden can ascend to Notodden. It is planned to enlarge the locks so as to allow the passage of seagoing vessels of 2000 tons. This ability to ship directly to all parts of the world by water is an important factor in the future of the Notodden nitrate industry.

The Importance of Water Power

The Notodden factories, which now have ca. 60,000 hp. in working, get this power from two neighboring waterfalls, Lienfos and Svaelgfos.

The equipment of the hydro-electric plants was described by Dr. Eyde in some detail. For transportation it was necessary to build railways and provide ferry-boats, and the the end of the development has not yet been reached. At the Rjukan waterfalls it is intended to build two power stations which will furnish the factories with 250,000 hp.

Dr. Eyde illustrated brilliantly the development of his industry by lantern slides showing the factories at different

times. In the beginning a few farmers were at the spot. Now there are towns with all the comforts of modern civilization.

According to the results of the use of their nitrate of lime, it is stated, that the use is the same as the Chile salpeter and for certain soils it is even better. Now they are sending many thousands of tons of Norgersalpeter to California and Hawaii to be applied in fruit orchards and sugar plantations; and the demand this year has been twice as large as last year.

The nitric acid and the nitrate of ammonia are also enjoying an excellent reputation.

The conclusion of Dr. Eyde's speech is perhaps more characteristic of the man than anything else. He spoke as follows:

"If you ask me what above all has contributed to such a rapid development of an industry, then I wish to mention the confidence the financial people gave me and the good collaboration between me and my engineers. We all were filled with the same thought, to create something great and useful for our country, and we all had in view the great importance this new industry would have from an international point of view.

"There is, however, one thing which I wish to tell you and which more than anything else has contributed to the great success obtained in the development in this industry, and that is that I mainly have employed young men for this work. This assertion may appear strange, but I assure you that it is the 'lack' of experience which has created this industry. If I had paid attention to all the doubt and hesitation brought forward by the so-called authorities during the development of our enterprise, the Norwegian nitrate industry of to-day would never have existed. Thanks to the young people, to their undaunted courage, energy and love of action, the work has been done, and it is in grateful remembrance of all our struggles I, as their boss, had with the men in joy and sorrow that I look backward to the work that has been done."

Young Men for Pioneer Work

At the conclusion of the lecture Dr. K. von Buchka, of Berlin, one of Germany's official representatives to the congress, offered the vote of thanks to Dr. Eyde, which was seconded by Mr. Bradley. Others who made complimentary references to the lecture and the lecturer were Dr. W. M. Johanessen, Chargé d'Affaires at Washington from Norway, and Dr. W. H. Walker, of the Massachusetts Institute of Technology, who was chairman of the meeting. Henry Fairfield Osborn welcomed the chemists to the American Museum of Natural History, and outlined a profitable hour's tour through the building.

One of the men who after the conclusion of Dr. Eyde's lecture went to shake hands with him was Mr. Bradley, to whose pioneer work Dr. Eyde had referred so gracefully in his opening remarks.

On the evening of Saturday a brilliant reception given by the American Chemical Society to the members of the International Congress of Applied Chemistry and to the members of the International Congress for Testing Materials was held in the Metropolitan Museum of Art in Central Park.

On Sunday a very enjoyable boat ride was made up the Hudson.

Monday Meetings of Congress Sections

Joint Session of the American Electrochemical Society with the Congress Sections of Electrochemistry and Physical Chemistry—Dr. Duisberg's Lecture

On Monday morning a very interesting joint session was held in Havemeyer Hall, chiefly devoted to subjects of **physical chemistry.**

The first paper presented was by **Theodore W. Richards** and **F. Daniels,** of Harvard University, on **the electrochemical behavior of very concentrated thallium amalgams.** In the absence of the authors it was read in abstract by Dr. W. H. Walker.

In continuation of previous work on this subject by one of the authors and Dr. J. H. Wilson, the electromotive forces between liquid amalgams of thallium of great concentration were carefully studied at various temperatures. From the temperature coefficients of these concentration cells the heats of dilution were calculated. It was found in every case that the observed electromotive forces greatly exceeded those calculated from the concentrations alone. If to the theoretical concentration effect is added the e.m.f. calculated from the best of solution, according to the equation of Cady, the agreement is much better.

The paper was discussed by Dr. W. Lash Miller, who was in the chair, by Dr. J. W. Richards and Dr. W. H. Walker.

Dr. Joel H. Hildebrand then read a very interesting paper on the **vapor pressure of amalgams** which led to a most interesting international discussion on the validity of the formulas based on the gas laws and on thermodynamics. The discussion was very stimulating and brought out the different standpoints very clearly as a real discussion should. Dr. Miller, Dr. von Antropoff, of Riga, Russia; Dr. Wilderman, of London, England; Dr. Forbes, Dr. Washburn and Dr. Hildebrand participated in this discussion.

Dr. Joel H. Hildebrand followed with the presentation of a second paper on **the relation between the potential of liquid amalgam cells and the constitution of the amalgam.** The paper was discussed by Dr. Forbes and Dr. Hildebrand.

Bioelectric Potential Differences.—A paper in German, by **Reinhard Beutner,** of the Rockefeller Institute for Medical Research, on "the physical nature of bioelectric potential differences" reaches the following conclusion:

Potential differences at the junction of an uninjured part of a plant and an aqueous solution of an electrolyte vary with the concentration of the electrolyte, as Dr. Loeb and the author have shown.

A formula was derived representing the relation between variation of potential difference and concentration. The formula was tested experimentally by means of measurements on apples. As required by the formula at high concentrations the difference of potential approaches a limit; at low concentrations the potential difference follows a simple logarithmic relation; the formula is also valid for intermediate concentrations.

If we assume that variations in potential difference induce stimulation, it is possible from the results obtained and with aid of Nernst's theory of stimulation to explain some electrophysiological observations; examples of which are (1) the different effect on stimulation of cathodical closing and of anodical closing; (2) the diminution of irritability in hypertonic salt solutions.

Mineral Electrodes.—A paper on mineral electrodes by **Roger C. Wells,** of the U. S. Geological Survey, Washington, D. C., points out that it is generally known that pyrolusite, magnetite, and pyrite are conductors of electricity, but it does not seem to have been recognized that a number of other sulphides are even better conductors than pyrite and can consequently serve as electrodes. The object of this preliminary paper is to set forth some of the phenomena which have been discovered to occur when conducting minerals function as electrodes in aqueous solutions.

The minerals studied, in the approximate order of their conductivity, are galena, pyrrhotite, magnetite, chalcopyrite and pyrite. These substances are attackable in various degrees in the process of electrolysis, depending upon whether they function as cathode or anode. As voltaic electrodes some of them develop potentials which are comparable with those shown by the metals in contact with solutions of their salts.

The results of experiments with electrodes of pyrite, magnetite, and galena, and the potentials of these electrodes against a standard electrode, are given together with some theoretical considerations.

These two papers were read by title in the absence of the authors.

Dr. G. A. Hulett then presented three very interesting papers on **G. A. Hulett** and **G. D. Buckner** on **the silver coulometer,** by **J. Stanley Laird, G. D. Buckner** and **G. A. Hulett** on **inclusions and impurities in electrolytic silver** and by **J. Stanley Laird** and **G. A. Hulett** on a **cadmium coulometer and the electrochemical equivalent of cadmium.** These papers elicited quite some interesting discussion

Joint Meeting of Sections on Electrochemistry and Metallurgy—Lecture on Boron.

The first paper presented at the afternoon session dealt with **The Distribution of Impurities in Steel Ingots** and was delivered in abstract by the author, **Vladimir Yakovleff,** of St. Petersburg, Russia. The author illustrated his remarks with numerous photographs, etchings and sulphur prints of sections of steel ingots. The paper has not yet been printed by the congress, having been received too late to be included in preliminary publications.

Following this speaker, **S. A. Tucker** presented an abstract of a paper on the **Fixation of Nitrogen by Aluminium and Carbon,** which was prepared jointly by himself and **Henry L. Read.** This paper will be abstracted at some length in our next issue.

The Iodine Coulometer and the Value of the Faraday was then presented by **E. W. Washburn** and **S. J. Bites,** of the University of Illinois, comparing the iodine coulometer with the silver coulometer and finding several points of advantage in the former.

This was followed by the principal lecture of the afternoon on **Boron, Its Compounds and Uses,** by Dr. **E. Weintraub,** of the Lynn laboratories of the General Electric Company. This was an experimental lecture reviewing the results attained during the past six years' research.

Dr. Weintraub briefly described two methods for the preparation of pure boron. According to the first method finely divided magnesium is brought into reaction with boric acid anhydride. The product obtained averages 98 per cent boron and further purification is carried out in a special mercury arc furnace. The melting point of boron lies above 2300°. According to the second method pure trichloride of boron is reduced by pure hydrogen, resulting in a very pure product. This is the method used for making boron regulators. The boron powder obtained is electrically melted together into solid lumps or rods, the lining of the furnace being made of boron nitride, the only substance found that will not contaminate melted boron. Furthermore, boron nitride is the most infusible refractory known.

Dr. Weintraub dwelt at length on the exceptionally high specific resistance of boron, 2×10^6 ohms, and its large negative temperature coefficient of resistance, the values being considerably higher than those for carbon and silicon. A strip of boron showed a resistance of 775,000 ohms at 27° C., 7 ohms at 520° C. and a small fraction of an ohm at 1000° C. Boron is hard and tough and has been successfully substituted for sapphire as a bearing jewel in electrical meters. Boron welds easily to all metals providing the weld be made in vacuum or in hydrogen. Slight impurities affect the general properties of the metalloid very markedly. Boron filament lamps have been found to be splendid voltage regulators. This was demonstrated in a number of experiments. In one of these a tungsten lamp was connected in parallel with a regulator, the higher the line voltage the greater the amount of current passing through the boron filaments, whereas the current through the tungsten filament remains practically constant.

The Latest Achievements and Problems of the Chemical Industry.

A Public Lecture by the Representative of Germany.

On the afternoon of September 9 Geheimrat **Dr. Carl Duisberg** delivered the public lecture in the College of the City of New York as the representative of Germany. It was a comprehensive and interesting lecture.

The Scope of the Chemical Industry

"Probably in no domain of human knowledge and endeavor have the combined forces of theory and practice, intimately acting and reacting upon each other, made such immense strides and led to the solution of such difficult problems as the chemical industry, an industry which, indeed, had its beginnings in the distant past, but in its vast development and international character is essentially a child of modern times. Success has so emboldened this industry that it considers itself capable of solving any problem, provided the men in its service are well trained in theory and practice and ready to devote themselves to the best of their ability, with patience and perseverance, to the object in view.

"This has been shown by the struggle between the contact process of producing sulphuric acid and the old chamber process; by the rivalry between the Solvay process and the Le Blanc method in the manufacture of soda; by the production of nitric acid and its salts by direct oxidation of nitrogen of the air under the influence of the heat of the electric discharge; by the manufacture of ammonia from atmospheric nitrogen indirectly via calcium cyanamide, and directly by combination with hydrogen; by the replacement of madder by alizarine, and of natural by synthetic indigo, as well as by innumerable other instances in the color, perfume and pharmaceutical industries.

"In the spirit of Faust: 'Who brings much will bring something to many.' I invite you to make a flight with me in an airship, as it were, over the fields where the chemical industry holds sway and, from our point of vantage, to take a bird's-eye view of the latest achievements of this industry."

In discussing the production of power it was interesting to hear Dr. Duisberg express the opinion that the advance of the steam turbine has already been surpassed by benzine, petroleum or oil engines (Diesel engines), and, above all, by the reliable gas engines which are driven by blast-furnace gases, Mond gas, and, more recently, by peat gas.

In discussing the production of by-products he remarked: "The latest and most rational method of utilizing the peat or turf beds, which are so plentiful in Germany and in many other countries, is practiced in Schweger Moor, near Osnabrück, according to a process discovered by Frank and Caro. There peat gas is produced and utilized and ammonia obtained as a

by-product, the required power being generated in a 3000-hp central electric power station. The moorland, after removal of the peat, is rendered serviceable for agricultural purposes."

Concerning production by cold, the following remarks were particularly interesting: "It is hoped in the near future to to produce refrigerating machines, which, by the use of suitable hydrocarbons, will give temperatures of minus 80 deg. C. Plants for the liquefaction of air, producing as low a temperature as minus 190 deg. C., are becoming more and more common and are especially profitable where gas mixtures, rich in oxygen, or where pure nitrogen, simultaneously produced, can be utilized.

Production of Cold

"The Badische Anilin & Soda Fabrik, in Ludwigshafen on the Rhine, intends to manufacture hydrogen from water gas in a similar way and to utilize the carbon monoxide, which is simultaneously obtained, as a source of power. In a large plant which is being erected, the firm is going to produce ammonia synthetically by combining, according to Haber's invention, pure nitrogen, obtained by the liquefaction and rectification of air, with hydrogen manufactured as above."

As to the size of chemical apparatus, Dr. Duisberg said that "influenced by the Solvay process for the manufacture of soda and its pecuniary advantages, the apparatus used in the chemical industry have enormously increased in size. In this respect the United States, no doubt on account of the example set by the iron industry with its blast furnaces with a daily capacity of 500 tons; its giant conveyors (50-ton wagons), its huge hoisting cranes, is ahead of other countries. But careful calculations have proved that there is a limit in this direction.

"The failure, on account of size, of the Mactear sulphate furnace, with a daily output of 25 tons, is well known, while the mechanical sulphate furnace of the Verein Chemischer Fabriken, in Mannheim, which produces only 7 tons a day, is a success everywhere. It is not improbable that the high cost of construction and the great loss which accidental stoppage entails will necessitate a reduction in size of the wonderful Wedge furnace, a creation of the United States, which roasts 30 tons of iron pyrites per day."

In discussing the material for chemical apparatus, Dr. Duisberg referred to quartz vessels, refined steel, alloy steels like nickel steel, chromium, tungsten, and molybdenum, vanadium, manganese, silicon steel, electric steel, and electrolytic iron.

Concerning the resistance to destructive effects of acids, Dr. Duisberg stated that "if alloys of iron with chromium, tungsten, molybdenum and aluminium in certain proportions are thermically treated, this resistance is increased five-fold, as is shown by samples of ordinary carbon steel and chrome-nickel steel which underwent a treatment with dilute sulphuric acid for fifty-six days.

Special Steels for Chemical Industry

"An alloy of ordinary iron with 5 per cent nickel is an excellent material for withstanding hot caustic soda. Most astonishing properties are displayed by steel alloys containing more than 10 per cent of chromium and a small addition (2 to 5 per cent) of molybdenum. Such alloys are manufactured in the form of malleable cast and forged iron pieces by Krupp according to the patents of Borchers and Monnartz in Aix-la-Chapelle and in the form of rolled tubes by the Mannesmann Röhrenwerken in Remscheid. These alloys are insoluble not only in dilute hydrochloric acid and sulphuric acid, but also in dilute nitric acid, even with the addition of alkali chlorides, and if they contain about 60 per cent chrome, 35 per cent iron, and 2 to 3 per cent molybdenum they withstand even boiling aqua regia.

"Of great importance are those alloys of iron with chromium, tungsten, and vanadium which possess a high degree of hardness, even at 400-500 deg. C. They are needed by engineers for the construction of steam turbines, for the embossing and spraying of metal objects when heated to redness, a process which has lately found extensive application. Chemists use these kinds of steel whenever chemical reactions are carried out at high temperatures and pressure, *e.g.*, for the synthesis of ammonia according to Haber's process.

"The very latest alloy has now been patented and is being manufactured by Krupp for the construction of safety vaults and safes. This steel can neither be drilled nor exploded, nor can it be cut by the oxy-hydrogen flame."

As to electrolytic iron made by the Fischer process by Langbein-Pfanhauser & Company, Dr. Duisberg said that it was formerly impossible "to produce it free from hydrogen, consequently it was hard and brittle and was not malleable. Only by electrolyzing at 100 to 120 deg. C. and employing an iron salt solution mixed with hygroscopic salts, such as calcium chloride, the iron became free from hydrogen. Its hardness then sinks far below that of silver and gold and is not much greater than that of aluminium. It possesses the valuable property of becoming magnetic more quickly than ordinary iron containing carbon or silicon, and also of again losing its magnetism more readily, thus considerably increasing the efficiency of electro-motors, for which it is used."

In discussing the manufacture of sulphuric acid, Dr. Duisberg referred to the splendid advance of the contact process. He said that nevertheless "the old lead-chamber process still competes with the new method, and the steady improvement of this process and the purity of the resulting acid must be acknowledged. In fact, the lead-chamber process promises to make further progress in the future in view of the success of Falding's high chambers and Opls towers in which large quantities of acid flow down.

Sulphuric Acid

"The Gaillard tower is supreme for concentration and recovery of the acid and for the regeneration of the various waste acids."

In respect to ammonium sulphate manufacture Dr. Duisberg said that "a new way of manufacturing sulphuric acid, together with ammonia, from the gases which are produced by the dry distillation of coal, is looming above the horizon. Burkheiser is seeking, with the aid of especially prepared wet iron compounds, to bind the sulphur, simultaneously absorbing cyan, and to convert the ammonium sulphite thus produced into ammonium sulphate by oxidation with atmospheric air.

"In competition with Burkheiser, Walter Feld is endeavoring to recover sulphur directly as ammonium sulphate by a series of interesting reactions, in which thiosulphates play an important part. Such plants are in operation in Königsberg and in New York."

As to nitrogen compounds, Dr. Duisberg referred with remarkably few words to the processes for the fixation of atmospheric nitrogen. "I will mention, however, that the problem of concentrating the dilute nitric acid, as obtained in the large absorption apparatus from nitrous gases, has been solved by Pauling's method, in which sulphuric acid is used in a battery of towers. It is also possible now to convert economically cyanamide into ammonia and this again into nitric acid."

As to soda and chlorine, the fifty-year-old Solvay process, which has conquered the whole world, still remains master of the situation. This is all the more remarkable since it is still imperfect as far as the yield is concerned, for a quarter of the salt used in the process is lost as such, and the whole amount of chlorine in the form of calcium chloride.

Caustic and Chlorine

"Although the materials employed in the LeBlanc process are completely utilized, this fact will not give it any chance of surviving, and it would seem to be now chiefly of historical interest.

"Not less remarkable is the twenty-five years' career of the alkali-chloride electrolysis. The limited market for chlorine compounds and the great space taken up by the electrolyzing baths were great obstacles to the progress of this apparently so

simple method. For the same reasons the most approved processes, such as the Griesheim cement cell, the quicksilver cathodes of Castner and his successors, the Aussing bell and the wire-gauze diaphragm of Hargreaves, with its many varieties, of which the Townsend cell is the latest and best, did not develop as expected. The limited demand also quickly restricted the operation of the brilliant method of manufacturing chlorates by electrolysis."

As to tin, electrolytic detinning and the chlorine detinning process of Goldschmidt were mentioned.

As to reducing and oxidizing agents, one of the "most brilliant successes in applied chemistry has been achieved by the persevering experiments of some chemists with a long-neglected substance, the constitution of which had never been properly understood. The old hydrosulphite of Schützenberger, rendered stable and easily transportable in powder form as an anhydrous sodium salt or as Rongalite in combination with formaldehyde, has now become a most important article of commerce. It is chiefly used in vat dyeing and for reducing purposes in general, such as stripping dyed fabrics and as Decrolin for bleaching sugar.

Hydrosulphite

Dr. Duisberg then referred briefly to peroxide of hydrogen, persulphates and perborates, rare metals and artificial gems. "Artificial rubies and white, yellow and blue sapphires, which cannot be distinguished from natural stones, are being manufactured in great quantities in Paris and recently also by the Elektrochemische Werke, Bitterfeld.

In passing over to applied organic chemistry Dr. Duisberg discussed the industries of coal tar, distillation of coal tar, organic intermediate processes, and coal tar colors.

"While people were formerly content to produce with coal-tar colors every possible shade in undreamt-of brightness in the simplest way, they gradually began to make more and more exacting demands as regards fastness. Not only had materials to be dyed a pleasing shade, but they also had to be fast to washing and light. Thus new, alluring problems were submitted to the color-chemist, and his indefatigable efforts have already carried him a long way toward the desired end. Strange to say, among the public, you will frequently meet the view that artificial colors do not give fast dyeings. This is a decided error which cannot be too emphatically contradicted. To-day we can produce almost any shade with any desired degree of fastness on any kind of material, whether it be wool, cotton, silk or paper."

"The old colors, though not as fast as those more recently discovered and though, perhaps, quite fugitive in some respects, still have a right to exist. It would be quite foolish to dye certain kinds of paper intended to be in use for only a very short time with colors absolutely fast to light, or to dye cloth never to be washed with expensive colors fast to washing, or, again, to treat lining, which is but slightly exposed to sunlight, in the same way as materials which must be exceedingly fast to light."

Colors

As to indigoid colors, "the synthetic production of colors allied to indigo was stimulated by the successful synthesis of indigo which almost entirely displaced natural indigo and called the attention of both chemist and consumer in an increased measure to the advantages of vat-dyeing. The king of dyestuffs, indigo, now finds itself in the company of a whole series of other colors, the brome indigos, the thio indigos and alizarine indigos, the shades ranging from blue to red, violet, gray and black."

Dr. Duisberg referred to indianthrene and algole colors, lake colors and then passed over to pharmaceutical chemistry.

"This industry is the youngest daughter of the coal-tar industry and it is not long since she celebrated her twenty-fifth anniversary. Those who, like myself, had the good fortune to stand at her cradle when Ludwig Knorr discovered antipyrin, and to guide her first tottering steps at the time phenacetin and sulfonal were brought out, must look back with a joyful heart to this period of splendid growth. Much brilliant work has been accomplished but a vast amount still remains to be done."

Dr. Duisberg then discussed chemotherapy, synthetic perfumes and acetylcellulose:

"From acetylcellulose soluble in aceton, called cellit, the Farbenfabriken vorm. Friedr. Bayer and Company first produced cinematograph films, but although they have the great advantage over those manufactured from nitro-cellulose in being non-inflammable, it has not been possible to introduce them generally. In all their properties the cellit films are equal to the old inflammable ones, yet the proprietors of moving picture theaters do not take them up because they fear the competition of the schools and the home where the cellit films would be largely used on account of their non-inflammability."

As to non-inflammable celluloid, "the problem of manufacturing non-inflammable celluloid by mixing cellit with suitable camphor substitutes which burn difficultly or not at all may be considered as definitely solved."

Finally Dr. Duisberg referred "to one of the greatest successes and yet one of the most difficult problems of the chemical industry, viz.: the production of synthetic rubber. I am proud of the fact that its production was successfully accomplished in the works which are under my management, and that I was able to follow every stage of this important discovery. Perhaps you would be interested to hear, although it is getting late, how the whole thing happened, especially as much that is untrue and misleading has appeared in the press during the last few weeks."

Artificial Rubber

"Caoutchouc is made from the milky sap of numerous species of trees and shrubs and the grotesquely formed lianas by various coagulation processes, and that this product, on being suitably treated with sulphur or sulphur compounds, i. e., by vulcanization, acquires its valuable and characteristic properties. The synthetic method took quite a different route. By breaking up the very complex molecule which rubber doubtless possesses, by pyrogenetic processes, i e., by dry distillation, a veritable maze of all kinds of gases, oils and resins was obtained, as well as a colorless fluid resembling benzine, to which the investigators gave the name 'isoprene.' It was the French scientist Bouchardat who first expressed the belief that this isoprene, which is obtained in very small quantities and in an impure form by the dry distillation of caoutchouc, might be closely and intimately related to caoutchouc itself. This important question was then eagerly discussed for several decades by the scientists of all countries and opinions were sharply divided. As far back as the Eighties the Englishman Tilden claimed to have prepared artificial rubber from isoprene by treatment with hydrochloric acid. But neither Tilden nor his assistants, though they worked strenuously for years, succeeded in repeating the experiments. Moreover, numerous other investigators were unable to confirm the results.

"Dr. Fritz Hofmann of the Farbenfabriken vorm. Friedr. Bayer & Company is to be regarded as the real discoverer of synthetic rubber, for, by the application of heat, he succeeded, in August, 1909, in polymerizing the isoprene molecules into the complex rubber molecule. Somewhat later Harries discovered independently another method of arriving at the same result. Everyone is now in a position to repeat this exceedingly simple experiment himself, but in order to confirm Hofmann's results, it is necessary to employ pure isoprene.

"Isoprene belongs to the butadienes. It was therefore to be assumed at the start that betamethylbutadiene would not hold a peculiar and isolated position among the butadienes in general. It was argued that other members of this interesting group of hydrocarbons would yield analogous and homologous rubbers on being heated. In the synthesis of products occurring in nature, there is always a possibility of producing such variations, and our endeavors to find out whether this was true in

the case of rubber were crowned with success, for to-day several representatives of the new class of caoutchoucs possessing different properties are known and are being submitted to technical tests. Exact proof of the existence of the class of isomeric and homologous caoutchoucs was also first presented by Elberfeld.

The Present Situation in Rubber

"The difficulties which have been overcome were great indeed and those which still remain to be surmounted, in order to produce a substance equal to para caoutchouc in quality and capable of competing with cheap plantation rubber costing only 2 marks per kilo, are still greater. But such difficulties do not intimidate the chemist and manufacturer; on the contrary, they spur them on to further efforts. The stone is rolling, and we will see to it that it reaches its destination. The end in view is this: that artificial rubber may soon play as important a rôle in the markets of the world as does natural rubber. The consumption of rubber is simply enormous. Finished articles to the value of 3 milliard marks are manufactured every year, and the raw material from which they are made, calculated at the present market price of 12 marks per kilo, costs one milliard marks. Other tasks which the chemist has on hand shrink into insignificance compared with this gigantic problem. The laurel wreath will not adorn the brow of the wild dreamer but that of the scientist who, cool and persevering, pursues his way. The seed he sows ripens slowly, and though according to the statements in the press, all this is mere child's play and the problem has been solved, I leave it to your judgment whether this is true or not, like much that printer's ink patiently transfers to paper. I am right in the midst of this excitement. I have employed articles made of synthetic rubber, and for some time I have used automobile tires made of this material. Yet, if you ask me to answer you honestly and truly when synthetic rubber will bring the millions which prophets see in its exploitation, I must reply that I do not know. Surely not in the immediate future, although synthetic rubber will certainly appear on the market in a very short time. But I hope to live long enough to see Art triumph also here over Nature."

Dr. **Leon Lindet,** of Paris, President of the Second International Congress of Applied Chemistry, moved a vote of thanks, which was seconded by Dr. **Arthur D. Little,** of Boston. Dr. Little referred to American enterprise and capital, which he spoke of in most commendable terms though he was tempted to class the attitude of the Americans toward the chemist as somewhat similar to that of the two haughty sisters toward Cinderella. But he prophesied that a prince was coming to take the chemist Cinderella forth into righteous glory.

Dr. Duisberg not only interestingly illustrated his lecture but offered a very valuable collection of products giving a graphic idea of the chemical industry, for the inspection by the audience.

Section on Analytical Chemistry.

The papers presented on Monday, Sept. 9, in this section were as follows:

On the Detection and Separation of Aluminium and Beryllium By the Action of Amyl Alcohol on the Nitrates.—By *Philip E. Browning* and *Simon Kurzirian.*

A Colorimetric Method for Titanium.—By *Victor Lenher* and *W. G. Crawford.*

The Influence of Lead on the Ferrocyanide Titration of Zinc.—By *Victor Lenher* and *C. C. Meloche.*

Analyse de l'Acide Vanadique Commercial.—By *G. Chesneau.*

A Proposed Standard Method of Analysis for Zinc.—By *Frank G. Breyer.*

A Rapid Estimation of the Amount of Cadmium Present in Zinc Ores and Products.—By *Frank G. Breyer.*

A New Method of Spelter Analysis.—By *Eric John Ericson.*

The Electrolytic Determination of Zinc.—By *Ellwood B. Spear.*

Section on Inorganic Chemistry.

The following is the program of this section for Monday, Sept. 9:

The Action of Potassium Amide on Thallium Nitrate in Liquid Ammonia Solutions.—By *Edward C. Franklin.*

The Anhydrous Condition and Stability of Lithium Perchlorate and Their Bearing Upon the Atomic Weight of Silver.—By *Theodore W. Richards.*

Sur la Nomenclature des sels Complexes de la Chimie Minerale.—By *G. Urbain.*

On the Effect of Free Chlorine Upon the Product of Hydrolysis of Tellurous Chloride.—By *Philip E. Browning* and *George O. Oberhelman.*

Atomic Weight of Phosphorus.—A paper by **Gregory Paul Baxter** and **Charles James Moore** of Harvard University deals with a revision of the atomic weight of phosphorus and the analysis of phosphorus trichloride. The authors describe methods for the preparation of pure phosphorus trichloride and its analysis.

The molecular weight of phosphorus trichloride referred to silver 107.880 is found to be 137.389, whence phosphorus has the atomic weight 31.018.

Using the same value for silver, the average result of the analyses of silver phosphate, phosphorus tribromide and phosphorus trichloride is 31.028, while the average of the more reliable tribromide and trichloride analyses is 31.023.

Atomic Weight of Iron.—A paper by **Gregory Paul Baxter** and **Charles Ruglas Hoover** of Harvard University is a further contribution to their revision of the atomic weight of iron, this being the fifth paper on the subject. The chief results are as follows:

Pure ferric oxide on reduction in hydrogen is found to contain 0.699427 per cent of iron, whence the atomic weight of iron is 55.847. Terrestrial and meteoric material are found to give identical results. When the result of this investigation is combined with that of the analysis of ferrous bromide by Baxter, Thorvaldson and Cobb, the atomic weight of iron is found to be 55.84.

Sodium as a Reducing Agent for Chlorides.—A paper by **Matthew A. Hunter,** of Troy, N. Y., deals with the reduction of some metallic chlorides by sodium, the chief results being as follows:

Titanium tetrachloride may be readily reduced by sodium in a closed bomb. If the amount of the material used be sufficiently great, the heat of the reaction is sufficient to give the titanium metal in a coherent metallic condition.

Carbon tetrachloride and carbon disulphide may be reduced by sodium. The temperature and pressure produced by the reaction is considerable. There is no conclusive evidence of the fusion of any part of the material during the reduction. A crystalline residue, microscopic in amount, appears to possess some of the properties of crystalline carbon.

By the reduction of the tetrachloride and disulphide of carbon with sodium, some sodium carbide is produced as a by-product of the reaction. With too little sodium to complete the reduction of the tetrachloride some carbon hexachloride is produced.

Beryllium chloride may be readily reduced by sodium and obtained in the metallic condition. Its properties will be further investigated.

Silicon tetrachloride may be reduced only with difficulty by sodium. Considerable trouble was experienced in maintaining an airtight bomb. The metal obtained was in a finely divided condition.

Neodymium chloride is reduced by sodium. The metal was found in a finely divided condition and could not be readily separated from the sodium chloride produced by the reaction.

Section on Explosives.

At the Monday session of this section the following papers were presented:

Detonator Troubles at Panama Canal.—By *Arthur Lee Robinson.* An abstract of this paper will be given in our next issue.

Neue Initialzundung fur Sprengstoffe.—By *H. Brunswig.*

Improved Densimeter.—By *W. O. Snelling.*

Improvements in Methods of Testing Explosives.—By *James Moir.*

Internationale Regelung der Vorschriften uben den Post-Eisenbahn und See-Transport Explosiver, Leicht Brennbarer, Atzender, etc., Products.—By *C. Gopner.*

Modified Stability Test for Nitro-Cellulose Powders.—By *H. C. P. Weber.*

Determination of Exudation of Nitroglycerine from Dynamites.—By *C. P. Beistle.*

Section on Organic Chemistry.

The following papers were presented at the Monday session of this section:

Ethyl, Isobutyl and Isoamyi Isourea.—By *R. H. McKee* and *A. M. Buswell.* An abstract of this paper will be given in our next issue.

The Kinetics of the Inversion of Sucrose by Invertase.—By *C. S. Hudson.*

Sur les Cyanhydrines de Quelques Monosaccharides.—By *C. Krauz* and *J. Kloud.*

The Chemistry of Wood. The Resins of the Douglas Fir.—By *G. B. Frankforter* and *H. H. Brown.*

The Relative Yields Obtained by the Destructive Distillation of Different Forms and Species of Hardwood.—By *L. F. Hawley and R. C. Palmer.* An abstract of this paper will be given in our next issue.

The Salts of Acridine, Pyridine and Quinoline.—By *L. H. Cone.*

Note on the Preparation of Benzylamine.—By *M. O. Forster* and *H. M. Judd.*

Structure of the Azoimide Nucleus.—By *M. O. Forster.*

The Preparation and Properties of 5-Aminoquinoline, 6-Carboxylic Acid and Certain Related Compounds.—By *M. T. Bogert* and *H. L. Fisher.* An abstract of this paper will be given in our next issue.

The Synthesis of 1, 3, 7-Naphthoisotriazines; a New Heterocyclic System.—By *M. T. Bogert* and *H. L. Fisher.* An abstract of this paper will be given in our next issue.

The Organic Acid Amides and Their Metallic Derivatives as Acids and Salts of the Ammonia System of Acids, Bases and Salts.—By *E. C. Franklin.* An abstract of this paper will be given in our next issue.

Section on Coal Tar Colors and Dyestuffs.

The program of this section for Monday, Sept. 9, was as follows:

Quinonoid Addition as the Mechanism of Dyestuff Synthesis.—By *Arthur G. Green.*

Coal Tar Colors and Injury to Health.—By *E. E. Smith.*

Action des Alcalinaterreuc sur la Laine.—By *Th. Valette.*

The Occurrence of Pentosans and Their Hydrolization Products in Corn and Corn Products.—*Christian E. G. Porst.*

Estimation of Cellulose; Cellulose Methods versus Crude Fibre. (Rohfaser) Methods.—By *C. T. Cross* and *E. J. Bevan.*

Analyse von Holzzellstoffen.—*Karl G. Schwalbe.*

The Distillation of Resinous Wood by Saturated Steam.—By *L. F. Hawley* and *R. C. Palmer.*

Antiseptic Tests of Wood Preserving Oils.—By *A. L. Dean* and *C. R. Downs.*

Action de la Formaldehyde sur les Soies Artificielles, les Amidons et les Cellyloses, Applications et Teinture.—By *Francis J. G. Beltzer.*

Section on Industry and Chemistry of Sugar.

The following is the program of this section for Monday, Sept. 9:

Einfluss der Beleuchtung auf das Wachstum der Samenrube.—By *J. Strohmer.*

Inversion von Rohrzuckerlosungen Mittels Chlorammoniums.

Production of Alcohol and Sugar from the Sap of the Nipa Palm.—*H. D. Gibbs.*

An Electrolytic Apparatus for Invert Sugar Determinations.—By *B. B. Ross.*

How the Netherland Sugar Fabricants Are Being Kept Informed During Campaign About the Quality of the Raw Sugar Produced.—By *M. C. Hummelinck* and *J. A. van Laan.*

Contribution a l'Etude des Torteauc d'Ecume en Sucrerie.—By *Lindet et Charpentier.*

Notes on Porto Rico Sugar Manufacture.—By *G. W. Rolfe.*

Expanded Meissl-Hiller Table for Invert Sugar.—By *E. W. Rice.*

Section on Indian Rubber and Other Plastics.

The program of this section for Monday was as follows:

Ueber die Behandlung des Kautschuks auf Pflanzen unter Besonderer Berucksichtigung Eigener Reiseeindrucke.—By *Eduard Markwald.*

On Condensation Products of Phenols and Formaldehyde.—By *L. H. Baekeland.*

Investigation Into the Nature and Properties of Hevea Latex.—By *Clayton Beadle* and *Henry P. Stevens.*

Section on Fuels and Asphalt.

The Monday program of this section is as follows:

Our Anthracite Coal Supply and Its Conservation.

The Production and Utilization of Peat for Power Purposes with Special Reference to the Korting Peat Producer Gas Power Plant Installed at the Fuel Testing Station of the Department of Mines, Ottawa, Canada.—By *B. F. Haanel.*

Section on Paints, Drying Oils and Varnishes.

The program of this section for Monday, Sept. 9, is given below:

The Rarer Paint Oils.—By *H. A. Gardner.*

A Critical Review of the Laws and Specifications of Linseed Oil.—By *O. Eisenschimmel.*

The Naval Stores Industry, Its Past, Present and Future.—By *C. H. Herty.*

Section on Starch, Cellulose and Paper.

The program of this section for Monday, Sept. 9, was as follows:

Research on Lintner's Starch Determination Method.—By *Christian E. G. Porst* and *H. A. Crown.*

Scientific Control in Sulphite Pulp Manufacture.—By *Charles M. Bullard.*

Resources and Conditions in the States of Washington for Paper Making.—By *Guy C. Howard.*

Notes on the Preparation of Chemically Pure Dextrose.—By *H. F. Bauer.*

Polarimetrische Starkebstimmung in Kartoffels.—By *Franz Herles.*

The Occurrence of Pentosans and Their Hydrolization Products in Corn and Corn Products.—By *Christian E. G. Porst.*

Estimation of Cellulose; Cellulose Methods Versus Crude Fibre (Rohfaser) Methods.—By *C. F. Cross* and *E. J. Bevan.*

Analyse von Holzzellstoffen.—By *Carl G. Schwalbe.*

The Distillation of Resinous Wood by Saturated Steam.—By *L. F. Hawley* and *R. C. Palmer.*

Antiseptic Tests of Wood Preserving Oils.—By *A. L. Dean* and *C. R. Downs.*

Action de la formaldehyde sur les soies artificelles, les amidons et les celluloses, applications et teinture.—By *Francis J. G. Beltzer.*

Section on Fermentation.

The program arranged for this section Monday, September 9, is given below. In the absence of the author, the paper was read by title.

Ueber die Konidienbildungsfachigkeit einiger Varietaeten des Aspergillus Oryzae.--By *G. Kita.*

Haupthefe der Sojamaische By *G. Kita*

La Diastase Saccharifiante de Malt et la Reaction du Milieu.—By *H. Van Laer*

Further Research on the Proteolytic Enzymes of Malt.—By *Robert Wahl.*

Inorganic Colloids for Clarifying Liquids.—By *F. E. Siebel.*

Recent Progress in the Study of Yeasts and Fermentation.—By *Wyatt, Schlichting, Winther.*

The Laws of Man in Relation to the Manufacture and Salt of Products Resulting from the Natural Law of Fermentation. -By *H. J. Kaltenbach.*

Red Yeasts.—A paper on "Red Yeasts" by **Kauzo Ando** of the Kiushu Imperial University of Fukuoka, Japan, gives an account of a research from which the author concludes that, although red yeasts exist in the ordinary air and in that of sake brewery, and would, therefore, appear likely to have some harmful effect upon the brewing industry, they have no direct influence upon it, their existence being limited by the amount of alcohol and acids contained in sake.

These yeasts may be classified under torula, as has been done by other investigators. The utilization of their power of liquefying gelatin and of inverting cane sugar must be made the subjects of future investigation.

Action of Koji Diastase on Starch.—A paper by **F. Ando,** Brewing Experiment Institute, Tokyo, Japan, gives an account of an experimental investigation on the saccharification of starch by Koji diastase in presence of acids and salts.

Section on Agricultural Chemistry.

The following papers were presented before this section on Monday, Sept. 9:

Biochemical Factors in Soils.—By *M. X. Sullivan.*

Some Constituents of Humus.—By *E. C. Shorey.*

Organic Soil Constituents in Their Relation to Soil Fertility. —By *Oswald Schreiner.*

Normal and Abnormal Constituents of Soil Organic Matter.—By *E. C. Lathrop.*

La Synthese des Corps Amides au Depens de l'Ammoniaque Absorbe par les Racines.—By *L. Prianischinkov.*

Organic Phosphorus of Soil.—By *John Stewart.*

Effect of Histidine and Arginine as Soil Constituents.—By *J. J. Skinner.*

Section on Hygiene.

The following is the program provided for this section on Monday, Sept. 9:

New Form of Apparatus for the Determination of Dissolved Oxygen in Water.—By *George A. Soper.*

A Practical Field Method for the Determination of Dissolved Oxygen in Water.—By *George A. Soper* and *P. B. Parsons.*

The Determination of Nitrates in Sea Water.—By *W. R. Copeland* and *George A. Soper.*

The Rational Use of Disinfectants and Algicides in Municipal Water Supplies.—By *K. F. Kellerman.*

Application of Chemistry to Industrial Hygiene.—By *C. T. Graham-Rogers.*

Section on Pharmaceutical Chemistry.

The program provided for this section on Monday was as follows:

Assay of Cinchona Bark. By *A. R. L. Dohme* and *Hermann Engelhardt.*

Quinine Alkaloid and Some of Its Compounds. By *George L. Schaefer.*

The Unification of Methods and Analysis of Essential Oils. By *Paul Jeancard* and *Conrad Satie.*

Unification of Processes for Commercial Analysis and Valuation of Essential Oils. By *John C. Umney* and *E. J. Parry.*

Analysis of Oil of Bitter Almond and Benzaldehyde. By *Francis D. Dodge.*

Section on Bromatology.

The program of this section on Monday, Sept. 9, was as follows. The papers having been printed they were briefly abstracted by the authors

Apparatus for Quantitative Extraction of the Gases in Canned Food Containers.—A paper by **H. A. Baker,** illustrating and describing apparatus for the purpose mentioned.

The Disappearance of Oxygen in Canned Food Containers.—The author, **H. A. Baker,** of New York City, states that oxygen is never, or rarely, present in the gas in the head space in cans containing food products. He ascribes the disappearance of the oxygen to its combination with the metals, tin and iron, or with the food, or with nascent hydrogen formed by the action of organic acids on the metal container.

Eggs Preserved with Silicate of Soda.—A paper by **J. M. Bartlett,** of Orono, Maine, giving results of experiments in preserving eggs in water glass solutions. The author concludes that eggs properly packed in water glass contain no more silica than fresh eggs; that the moisture content and nutritive value of these eggs are unaffected, and that they are superior to most cold-storage eggs.

Some Results of the Food and Drugs Act.—The author, **W. D. Bigelow,** is Chief of Division of Foods and Assistant Chief, Bureau of Chemistry, Washington, D. C. He discusses the effect of the Food and Drugs Act on misbranding, "slack filling," artificial coloring, preservatives, and sanitation, and commends the changed attitude of manufacturers toward violations of the law.

A Chemical Investigation of Asiatic Rice.—A paper by **Allerton S. Cushman** and **H. C. Fuller,** of the Institute of Industrial Research, Washington, D. C., describing results of an investigation made for the Siamese Government, on the relation of an exclusive rice diet to the etiology of the beri-beri disease. The authors conclude that there is no reason why white milled rices from one part of the world should be held more responsible for mal-nutrition than similar rices from other sections.

The Effect of Modifying the Gluten Surrounding of Flour.—A paper by **George A. Olson,** of Pullman, Wash., investigating the causes which affect the quality of flour for baking purposes. Flours were either made into dough with water, dialyzed or decanted, then dried, remilled and bolted into flour again. Gluten determinations were made, using different reagents in order to note differences in yield caused by modifying the surroundings.

The Chemist in the Service of the Packing House.—A paper by **Paul Rudnick,** of Chicago, Ill., discussing the relation of the chemist to the packing industry, under three headings, namely, analytical, research and consulting work. The author emphasizes the necessity of reporting chemical results to business men in simple language, avoiding as far as possible the use of technical statements.

Wheat Flour.—A monograph by **Harry Snyder,** of Minneapolis, Minn., discussing particularly the moisture content of flour and the basis upon which the results are reported. The author gives a critical discussion of the analytical methods used.

The Packing of American Sardines.—A paper by **H. H. Hanson,** of Orono, Maine, describing the sardine packing industry, and considering some of the difficulties encountered in canning the fish for market. The causes contributing to the breaking of fish during their preparation for market are considered and directions given to avoid this as far as possible. One of the principal sources of deterioration in sardines is "red feed."

The Microscopical Examination of Vegetable Products as an Adjunct to Their Chemical Analysis.—A paper by **A. L. Winton**, United States Food and Drug Inspection Laboratory, Chicago, Ill., advising of the more extended use by chemists of microscopical examinations of vegetable products, and giving instances of the use of the microscope in this work.

Progress Report of Nutrition Investigations in the United States.—A paper by **C. F. Langworthy**, of the Office of Experiment Stations, Washington, D. C., giving a summary of human nutrition investigations made since the Seventh International Congress of Applied Chemistry. The subject is treated extensively under the following heads: Studies of Food and Food Products; Special Studies of Ash, Protein and Other Food Constituents; Cooking in Its Relation to Nutritive Value; Canning, Preserving, Handling and Storage; Dietary Studies and Dietetics; Digestion; Metabolism; Respiration Calorimeters, Bomb Calorimeters, and Experiments with Them; Foods and Their Relation to Problem of Hygiene, and Cost of Living and Other Statistical Data.

Chemical Study of the Fruits of "Sorindeia Oleosa."—A paper in French by **Alexandre Hébert**, of Paris, France.

On the Composition of Various Products, Seeds or Amylaceous Tubercules of French West Africa.—A paper in French by **Alexandre Hébert**, of Paris, France.

A Chemical Investigation of Asiatic Rice.—by **A. S. Cushman** and **H. C. Fuller.**

Section on Biochemistry Including Pharmacology.

At the session of this section held on Monday, Sept. 9, the following program was provided:

Schnelles Verfahren zur Bestimmung der Harnsaure im Harn.—By **Franz Herles**, Prag, Bohem.

The Influence of the Gaseous Impurities of Air on the Vitality of Microbes.—A paper in French by **A. Crillat**, of Paris, France.

Quantitative Oxidase Measurements.—A paper by **Herbert H. Bunzel** of the United States Department of Agriculture, Washington, D. C., giving methods of determining the oxidizing power of certain plant juices.

Some Chemical Reactions of Microorganisms and Their Significance in Chemical and Biological Problems.—A paper in German by Felix Ehrlich, of Breslau, Germany.

Biochemical and Toxicological Studies on Penicillium Stoloniferum.—Thom.—A paper by **C. L. Alsberg** and **O. F. Black** of the United States Department of Agriculture, Washington, D. C., discussing the effect of molds on animals. From the cultures of Penicillium Stoloniferum Thom obtained from a sample of spoiled maize from Italy a new phenolic acid of the formula $C_{17}H_{20}O_6$, was isolated in crystalline form. It resembles the lichen acids, is not toxic and is one of the substances causing the ferric chloride reaction of Gosio in deteriorated maize.

Section on Photochemistry.

The following program was arranged for the section Monday, Sept. 9:

The Latent Image. By *Wilder D. Bancroft.*

The Electro Potentials of Certain Photographic Developers and a Possible Explanation of Photographic Development. By *J. H. Mathews* and *F. E. Barmeier.*

The Protective Action of Sulphite. By *W. D. Bancroft* and *M. A. Gordon.*

A Note on the Rôle Played by the Carbonate in Photographic Development. By *J. H. Mathews* and *F. E. Barmeier.*

The Effect of Bromide. By *Wilder D. Bancroft.*

The Silver Equivalent of Hydroquinone. By *W. D. Bancroft* and *M. A. Gordon.*

The Measurement of Reduction Potentials of Development.—A paper by **F. Austin Lidbury** giving the following conclusions:

The single potential: platinized platinum—developing solution varies in general considerably with the time elapsed since the preparation of the solution.

To obtain the constant final values, solutions should be stored two or three weeks after preparing or diluting.

Duplicate cells should be employed and results in which both cells do not agree discarded

The Influence of Dilution on the Reduction Potentials of Developing Solutions.—A paper by **F. Austin Lidbury**, giving the following summary:

The potential of the single electrode: platinized platinum-developing solution was measured for Hydroquinone, Amidol, Metol and Rodinal developers of standard composition and of the same diluted to ¼, 1/16 and 1/64 strength. No regularities are traceable between the developing peculiarities of the solutions and their reduction potentials.

The Effect of Changes of Composition on the Reduction Potential of Developing Solutions.—A paper by **F. Austin Lidbury**, giving the following conclusions:

The addition of sulphite to a developer consisting of sodium carbonate and hydroquinone or pyrogallol increases the reduction potential; the effect of the further addition of bromide was to lower it in the case of pyrogallol only.

The reduction potential of a developer consisting of hydroquinone and sodium carbonate is not affected (after constant values have been attained) by wide variations in the concentration of the carbonate.

The reduction potential of a developer consisting of hydroquinone and sodium hydrate increases with increasing concentration of the sodium hydrate up to 2½ per cent.

The reduction potential of a developer containing 4.4 grams per liter sodium hydrate and varying quantities of hydroquinone decreases with increasing hydroquinone concentration beyond 5 grams per liter.

The reduction potential of a developer of composition approximating 5 grams per liter hydroquinone and 5 grams per liter sodium hydrate first increases rapidly with time and subsequently decreases slowly to a constant value.

Section on Political Economy and Conservation of Natural Resources.

The program of this section for Monday, Sept. 9, was as follows:

The Waste Problems in the Anthracite Coal Industry. By *Eli T. Conner* and *William Griffith.*

Coal Waste. By *Metz.*

The Waste of Coal in Bituminous Coal Washings. By *G. R. Delamater.*

American Oil Shales. By *Charles Baskerville.*

Neuerungen auf dem Gebiete der Torfgewinnung und Torfverwertung. By *W. Wielandt.*

Ueber die Beziehungen swischen der Chemie der Erdole und der Geologie Derselben. By *M. A. Rakusin.*

Fuel Oil versus Coals. By *Irving C. Allen.*

The Production and Utilization of Peat for Power Purposes with Special Reference to the Korting Peat Producer Gas Power Plant, Installed at the Fuel Testing Station of the Department of Mines, Ottawa, Canada. By *B. F. Haanel.*

The Conservation of Forests by Private Landholders in the United States. By *Overton W. Price.*

What the United States is Doing in Forestry. By *Henry S. Graves.*

Conservation of Water Powers and Other Natural Resources in Chile. From notes furnished by the Chilean government through his excellency, the Chilean Minister, Washington, D. C.

Tuesday Meetings of Congress Sections

Symposia on Electrolytic Production of Caustic and Bleach and on Sulphuric Acid

The sections on Electrochemistry and on Paper held a joint meeting with the American Electrochemical Society on Tuesday, September 10, in the morning, in which four papers relating to the electrolysis of sodium chloride solutions were presented.

Professor Charles F. Burgess, of the University of Wisconsin, presided.

Cost of Hypochlorite.—A paper on "some factors in the cost of sodium hypochlorite production," by **Wm. H. Walker** and **Ralph E. Gegenheimer,** of the Massachusetts Institute of Technology, Boston, Mass., discusses the problem how the relation of the cost of salt and the cost of electric power influences the economy of the electrolytic process for the production of sodium hypochlorite. The less salt is used in the solution, the lower the cost of the solution, but the higher the cost of power per unit of available chlorine produced. The problem, however, is exceedingly complicated.

Increasing the amount of salt per gallon of salt solution used increases the total cost, because it—

1. Makes more expensive the first cost of the solution.
2. Causes a higher final temperature with heavy chlorate formation.
3. It increases the amount of current flowing and increases deterioration of electrodes.

It decreases the cost, because it—

1. Lowers the resistance to the current and consumes less energy.
2. Decreases chlorate formation at the anode.
3. Increases production of cell.

A rapid rate of flow of solution increases the final cost because it—

1. Increases the consumption of salt.

It decreases the cost—

1. Because it maintains a lower temperature, and prevents chlorate loss.
2. It maintains a lower hypochlorite concentration and prevents reduction at the cathode.
3. It lowers chlorate formation at the anode.

Increasing the amount of available chlorine per gallon of solution increases the final cost, because it—

1. Increases the reduction loss of the cathode.
2. Increases the oxidation loss at the anode.
3. Increases the temperature of outflowing solution.

But it greatly decreases the total cost, because it—

Makes more available chlorine per gallon effluent, and hence reduces the number of gallons of solution required for a determined amount of available chlorine.

If a large amount of salt is used, we will economize in electric power, and vice versa. The price which must be paid for salt and power varies at different localities, and the amount of salt and power which is most economical at one place may be the wrong amounts to use at another place where the costs are different. The question arises, therefore, how can the relationship between the cost of salt and cost of power be established, and how can such relationships be most conveniently expressed in order to be of general use?

In order to reduce the number of experiments necessary to answer this very complicated question, the authors designed an apparatus consisting of 24 compartments, the solution passing from one to the next, and so on. The apparatus was equipped with thermometers, and means of withdrawing samples for analysis in the 4th, 8th, 12th, 16th, 18th, 22d and end compartments. The run was commenced with a definite strength of salt solution, and the rate of flow was fixed as would give a strong bleaching solution in the last compartment. The current was allowed to flow for an hour or so, or until the apparatus came to equilibrium. That is, until the flow of current and the flow of solution into and out of the apparatus was constant, the temperature of the different compartments did not change, and the strength of available chlorine in the last compartment was constant. At this point the temperature in each cell was read, and a sample of the solution was taken from each of the cells equipped for the purpose, that is, 4, 8, 12, etc. The results of these tests were tabulated and show how the temperature of the solution increased as it passed through the apparatus, how the available chlorine is increased as measured in pounds per gallon, how the percentage of the current which has been utilized in making the desired product fall off as the end of the apparatus is reached. The power consumed per pound of available chlorine produced therefrom increases, while the amount of salt used per pound of available chlorine decreases as the solution becomes stronger in its bleaching power. This is true also of the cost of the two elements.

From the results obtained it is easy to figure the cost of power and the cost of salt per ton of available chlorine if the operation is stopped at the end of the 24 compartments. If these figures are calculated it will be found that the total cost of salt and power together per ton of available chlorine will be a minimum for a certain compartment. Under the conditions of the experiments of the authors it would be cheapest to stop the operation at the 12th compartment, where the available chlorine produced cost $0.1101 per pound. Beyond this point as the solution passed through the apparatus more hypochlorite is formed, but the expenditure for power is so large owing to chlorate formation and cathode reduction as compared to the saving in salt and the net cost of available chlorine produced becomes larger as we pass beyond the 12th compartment.

The experiment with the 24 compartments was made with current from a commercial 110-volt circuit. The question now arises how to use 12 instead of 24 compartments on the 110-volt circuit, and the answer is to run the salt solution through twice as fast as in the experimental run. While the additional rate of flow would of course maintain a lower temperature, and hence a somewhat smaller number of amperes would flow through the apparatus, the loss of hypochlorite through reduction would be greater, insomuch as that made in the first compartment is subjected to the cathodes of the following compartments, and the concentration of the hypochlorite would also increase more slowly, and hence the loss would be considerably smaller.

The paper finally refers to the feasibility of basing the calculations on the ratio of the cost of salt to the cost of power.

In the discussion the opinion was expressed that it would be cheaper to make hypochlorite solution from bleaching powder instead of producing it directly by electrolysis. It was explained, however, that laundries found it more convenient to use electrolytic hypochlorite cells since they could employ their electric lighting current for the operation of the cell and could make just as much bleaching liquor as they needed.

Dr. W. Lash Miller characterized the paper as a classic for an electrochemical engineering course.

The Commercial Development of Chemical Processes was the subject of a paper by **Jasper Whiting,** of Boston, Mass., describing the different steps in the gradual development of a chemical process from the first invention to commercial opera-

tion. The author is himself the inventor of two chemical engineering processes, one for making cement from blast furnace slag, and the other a cell for the electrolytic production of chlorine and caustic alkalies. The development of each of these two processes occupied approximately five years and though the two processes were very dissimilar, one being a chemical engineering and the other an electrochemical engineering problem, the means taken to achieve the final results and the periods of evolution were much the same in each instance.

The author distinguishes five different stages in the evolution of any chemical engineering process. First, the beaker or laboratory stage. Its function is to prove the correctness of the chemical principle involved, the novelty of the process and its commercial soundness.

The second stage, the small-sized model. Its function is to determine the best conditions of operations.

Third stage, life-sized unit. Its function is to determine, so far as possible, the final design of the apparatus

Fourth stage, the semi-commercial plant. It is the function of this stage to determine the efficiency of the apparatus when operated in multiple, and its relation to the necessary auxiliary equipment.

Fifth stage, commercial plant. The conditions to be considered in connection with this final stage are too many and too obvious to be spoken of in this paper. I would only suggest that the plant be laid out on a large and comprehensive scale, but on the sectional basis, and only one section built at first. If this section operates successfully, the development work is over and the process has reached the promised land.

Mr. Whiting's paper was discussed by Dr. Wilderman and Dr. Walker.

A New Mercury-Cathode Cell for the Electrolysis of Alkalis and Salt.

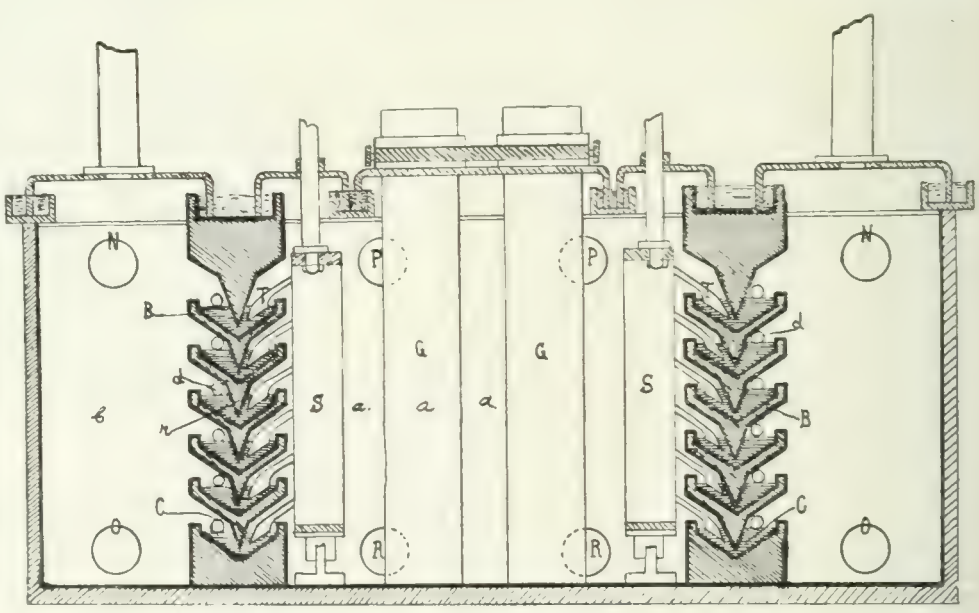
A paper on the recent progress in the electrolysis of alkalis and salts by **Dr. E. Wilderman, of** London, England, describes his cell which has been put up at the Zellstofffabrik Waldhoi, Mannheim, Germany, for a production of 10,000 tons of bleach per annum. It has been working very successfully from the first day till now without interruption for about 16 months, and this installation is now being increased for a production of 14 to 15,000 tons of bleach per annum.

The Wilderman cell consists of a decomposing compartment *a* and of a combining compartment *b*, which are separated by a partition composed of superimposed troughs containing a quantity of mercury which has free surfaces exposed in the combining and in the decomposing compartments. G shows the anodes. The inner compartment (*a*) contains a saturated solution of sodium chloride or potassium chloride, the outer compartment (*b*) contains caustic soda or potash of about 20 to 27 per cent. The current is passing from the anode G through the brine to the mercury in the troughs and from here back to the dynamo or to the next cell; alkaline metal is thus deposited by the current on the surface of the mercury and forms immediately therewith an amalgam, while the chlorine is separated on the anode G and is conducted away for the production of bleaching powder or chlorates, etc. Into the mercury of the troughs the teeth T of the stirrers S are dipping so as to effectually mix the amalgam formed on the top surface of the mercury with the mercury beneath it.

A special feature of the Wilderman cell is that in every and in all its parts it is built of iron covered with ebonite of Dr. Wilderman's invention which stands both caustic and chlorine excellently. One millimetre of this ebonite stands about eight years chlorine and is not affected at all by caustic. The cell combines the strength of iron as is requisite in the heavy chemical industry with the chemical strength and life of his ebonites and is capable to live 15 years and longer and practically requires no repairs.

Another special feature in the construction of the Wilderman cell is that the super-imposed troughs can be put *ad libitum* far from one another so that the surface of the anode is many times greater than that of the cathode. On this account the current density is very high upon the mercury surface, but comparatively small on the anode surface, so that graphite anodes instead of platinum electrodes can be used, and at the same time much greater current densities can be obtained with the same volts. This is not possible with the other cells where the anode is of necessity smaller but not larger than the cathode.

A third special feature of the Wilderman cell is that the mercury is placed in the vertical wall and not at the bottom of the cell and that it is supplied with stirrers which always keep the mercury surface perfectly clean from dirt which is important for the efficiency and the good work of the cell. All the dirt from the brine as well as the decomposed carbon settles at the bottom and not on the mercury. Contrary to this, all the dirt and the decomposed carbon settle down in cells with horizontal mercury or horizontal diaphragm on the mercury or the diaphragm itself. The Wilderman cell has also no diaphragms to replace so that there are no causes for interruption of its work. At the Zellstoffabrik Waldhof very cheap and inferior salt is used containing about 4 per cent. sulphates, calcium, magnesium, iron, slate, etc., and still the cell has to be cleaned only once in 6 to 8 months; with better salt it should work uninterruptedly for a year and longer.



WILDERMAN MERCURY-CATHODE CELL

The author then pointed out that the old method of bodily transportation of amalgam from the decomposing to the combining compartment leads to small current densities and makes the transportation artificial and limited to strict conditions of work; further that the new principle of transportation of amalgam by buoyancy leads to very high current densities; it

also makes the transportation self-regulating and independent of strict conditions of work; it makes the formation of solid amalgam impossible.

In discussing the important technical consequences of high current densities and high self-regulating properties in the Wilderman cell he made the following points:

"In the first instance we are able to work the power installation at its maximum capacity, that is, most economically, the same cells taking up automatically all the energy the power installation is capable to supply at any given moment.

"The higher current density leads to higher efficiency and the practically total absence of hypochlorites.

"High current densities lead to great economy in the cost of the installation and in the cost of production."

He finally referred to the production of caustic potash.

The author finally showed some comparative curves of current densities of different systems at the same volts per square centimeter of diaphragm or square centimeter of mercury cathode.

He also showed comparative curves of efficiency and concentration of caustic in different systems. The paper was discussed by Dr. Klemp, at whose plant the Wilderman cell is in operation in Germany; further by Mr. Whiting, Mr. Griffin and Mr. Hooker. The latter gentleman did not seem to be as much convinced of the advantages of the cell as the inventor.

Alkali and Chlorine-Proof Ebonite.—"A process for the manufacture of ebonites capable of resisting the action of alkalis and chlorine and its effect upon the industry of electrolytic decomposition of alkaline salts" is the subject of a paper by **Dr. M. Wilderman,** London, England. The manufacture of such ebonites is as follows:

Ten parts of chemically pure finely divided graphite, 33 parts of sulphur and 57 parts of Para rubber are intimately mixed to a homogeneous mass, and the mixture is then used for the preparation of ebonite plates, as well as for covering iron by hand or in molds in the known manner. The vulcanization is first conducted slowly, and the pressure gradually brought during a period of an hour to two hours to about three atmospheres and then kept at this pressure for a suitable time such as from 40 to 45 hours, until the requisite vulcanization is achieved.

The proportions given above may be varied and useful products will still be obtained but their results become worse the more we deviate from the given proportions. The speed with which the correct vulcanization takes place changes naturally with the temperature of vulcanization. It is greater the higher the temperature used.

The covering of iron with ebonite takes place in steel molds, under very great pressure; the methods requisite for this are now worked out to very great perfection and precision. We can cover any piece of iron with ebonite to any desired shape with a precision of 0.1 to 0.2 of mm., and the ebonite itself can be made to adhere to the iron so perfectly, that we may hammer it without breaking it off from the iron, unless violence is used. (This will be illustrated.) The vulcanization in case of covering of iron with ebonite does not require to be so long, as in the case of pure ebonites, evidently because of the iron being a good conductor of heat.

Generally speaking, the vulcanization for very good ebonite plates should last for 24 to 48 hours and in case of iron plates covered with ebonite the time of 12 to 24 hours should suffice. In this case the physical properties of ebonite such as elasticity and flexibility, are sufficiently preserved for the purpose. In any case the physical properties become somewhat affected through over-vulcanization, and the period of vulcanization should be varied according to the purpose in view in each individual case, and the necessary methods must be used to make the ebonite adhere perfectly to the iron.

The following papers were read by title:

A New Contribution to the Theory of Diaphragm Cells. By PH. A. GUYE (in French.)

Mechanical Depolarization in Electrolytic Cells. By ALAN V. CLAFLIN.

Industrial Uses of Chlorine. By RUD. TAUSSIG (in German).

Joint Meeting of Sections on Electrochemistry, Mining and Metallurgy, and Political Economy and Conservation

In the afternoon session of Tuesday a paper contributed by the section of electrochemistry was first presented.

Determination of Oxygen in Iron in Electric Vacuum Furnace.—A paper on the determination of oxygen in iron and steel by reduction in an electric vacuum furnace, by **Wm. H. Walker** and **Walter A. Patrick,** of the Massachusetts Institute of Technology, Boston, Mass., points out that Ledebur's method for determining oxygen in iron is defective in so far as at a high temperature hydrogen reduces only the oxides of iron leaving unattacked to a large extent the oxides of manganese, aluminium, silicon, titanium, etc. It is of great importance to have a method for measuring exactly the total oxygen in a sample, and especially that portion which is combined with manganese, aluminium, silicon, and the other oxides not reducible with hydrogen. The method described by the authors is based on the now well-known reaction wherein the oxides of the elements are converted into the corresponding carbides by heating them with an excess of carbon to a high temperature in an electric furnace, the oxygen being given off quantitatively as carbon monoxide. The quantitative formation of carbon monoxide is aided by an excess of carbon at high temperatures, and by a low pressure; also, as has been pointed out by Moissan, the refractory oxides are more readily reduced in the presence of metallic iron.

The authors use an Arsem vacuum furnace. The results of analysis given in the paper indicate a high accuracy of the new method and considerable inaccuracy in the Ledebur method. An instance is a special heat of an open-hearth steel to which iron ore and an excess of manganese was added in the ladle. The finished steel gave every evidence of having a high oxygen content, although, by the Ledebur method, but 0.006 per cent oxygen was obtained. When determined by the vacuum furnace reduction method the real oxygen content of the steel proved to be 0.20 per cent.

Then followed a most interesting experimental lecture by **Linn Bradley** on the **Electrical Precipitation of Dust and Fume.** Mr. Bradley is the New York engineer of the Research Corporation to which Dr. Cottrell assigned the patents on his process of electrostatic dust precipitation for the purpose of encouraging research. Dr. Cottrell himself will present a paper on the scope of the Research Corporation before the section on political economy and conservation on Thursday, and the paper will be duly reported in our October issue.

Dr. Cottrell's process was described in some detail in our Vol. 10, page 172. It is, therefore, not necessary to describe it again. Mr. Bradley demonstrated the process by showing the condensation of various kinds of fume and dust, and exhibited products which had been collected in commercial plants. (In connection with this the reader should refer to page 611 a paper by W. A. Schmidt, which refers to the application of the Cottrell process in a cement plant in Riverside, Cal.) Mr. Bradley's demonstration and experiments were exceedingly interesting, and we hope to publish his paper at greater length in a future issue.

The first paper considered Tuesday morning was by **Richard Zsigmondy** on **Disperse Systems of Colloids.** In the absence of the author, an abstract of the paper was presented by Mr. Jerome Alexander. A table was shown, exhibiting Zsigmondy's arrangement of disperse systems, as follows: I, in a gaseous disperse agent; II, in a fluid agent, and III, in a solid disperse agent. **J. W. Richards** commented on the increasing importance of the chemistry and physics of colloids in metallurgy, particularly with reference to metal losses in slags.

Section on Inorganic Chemistry

Symposium on Sulphuric Acid

Contact Sulphuric Acid from Brimstone.

A paper by **G. W. Patterson** and **L. B. Cheney,** of Indian Head, Ind., describes the plant erected in 1907 at the U. S. Naval Proving Ground, Indian Head, Md., for the manufacture of acid used in making smokeless powder. It was designed by the New Jersey Zinc Co., which controls the Schroeder patents in this country.

With a rated capacity of six tons, it was operated successfully for three years, burning pyrites from New York and Virginia in O'Brien burners. During the last two years, Louisiana brimstone has been used entirely. The reason for changing raw materials was primarily to increase capacity without enlarging the plant, and it was hoped incidentally to reduce costs, notwithstanding the large increase in price per unit of sulphur. The expectations have been fully realized in both respects.

The installation is described under four heads: burner and gas cooling system, gas purifiers, conversion system, and absorbing system.

The *burner* is known as the Tromblee and Paull burner and has been most satisfactory. It consists of a horizontal cylindrical iron shell 8 feet long and 3 feet in diameter with conical ends, revolving on its axis once in two minutes. At one end is a hopper and worm feed with sliding dampers. The other end connects with a rectangular cast iron box of 37 cu. ft. capacity, provided with sliding damper and vertical cast iron uptake pipe. This pipe leads to a brick dust catcher such as is ordinarily used with pyrites burners. The dust catcher merely cools the gas, as no appreciable amount of sulphur is carried beyond the combustion box.

The burner is rated at 5500 lbs. per day, but there has been no difficulty in burning 6000 lbs. per day. Before feeding to the hopper, the sulphur needs no other preparation than breaking up large lumps with a shovel. When forced along by the worm, the sulphur melts just before it drops into the body of the burner, and a sufficient amount of melted sulphur is always present to form a complete liquid coating on the inside of the shell as it revolves. The combustion box and vertical uptake complete perfectly to combustion of any sulphur which is volatilized from the cylinder.

The special advantages of this burner are ease in controlling composition of gas, low cost of upkeep, and freedom from losses. Once in about two months it is necessary to clean out the dross which collects in the cylinder. To do this, or to prepare for a shut-down for repairs in any other part of the plant, the sulphur charge is allowed to burn out completely. Any residue in the cylinder is then easily removed by a hoe. Starting the burner after cleaning, or even when it is cold, is a simple operation, and no losses occur.

At the exit from the dust catcher the gas has cooled to a temperature of about 230 deg. C. At this point it enters the *gas purifying* system, which consists first of 250 lin. ft. of horizontal lead pipe arranged in tiers in a wooden rack. All gas passes through this total length of pipe. This pipe is cooled by a water spray, and here is deposited a small quantity of weak sulphuric acid formed in burning the sulphur. The acid deposited is, however, slight in comparison with the amount collected at the same point when pyrites was burned. The lead pipe connects with a large lead-lined box containing coke and here a further deposit of weak acid is obtained. Up to this point also is formed a slight deposit of carbonaceous matter from the asphaltic material which Louisiana brimstone always carries in small quantities.

From the coke box the gas passes to two wet scrubbers in tandem. Each scrubber outfit consists of a vertical lead cylinder with conical top, about 4 ft. high, a lead pot provided with lead cooling coils for water, and an air lift for circulating constantly a stream of sulphuric acid from the pot to the scrubber The scrubber is divided horizontally by perforated diaphragms The acid washes and dries the gas thoroughly and flows out through trapped pipes in a weakened condition to the pot. A pot holds 2500 lbs. of acid and is constantly strengthened to a gravity of 1.75 by the addition of strong acid. The excess acid formed at this point is collected in an egg and can be forced by air pressure to the weak acid supply used in the absorbing system. The air lift was designed by one of the authors (Patterson) to replace the ordinary bubbler formerly used. Only 5 lbs. air pressure is used, raising 80 lbs. of acid per minute, and the top of the lift is gas-tight, the air being piped to the gas system preventing any loss of SO_2 at this point.

From the scrubbers the gas passes to a second lead-lined coke box exactly like the first one and thence to a pair of dry filters in parallel. Each dry filter consists of three superimposed lead-lined iron trays luted together. Each tray contains a mat of dry asbestos fibre supporting a quantity of slag wool. A reserve set of these filters is kept ready for use as they require to be renewed about once in four weeks. The entire charge for two filters is 30 lbs. of asbestos and 400 lbs. of slag wool. The dry filters complete the purification process and the gas is then carried into the main building. Throughout the purification process the gas comes in contact with no other metal than lead, but beyond this point either cast iron or wrought iron is used entirely.

Within the house, the gas first passes through a positive pressure blower, by regulating the speed of which the composition of the entrance gas is controlled, and the movement of gas through the whole system is completed. Manometers on either side of this blower show a suction of 1.5" of mercury and a pressure of 0.75" of mercury. Just forward of the blower is the sampling pipe where the composition of entrance gas is tested by the usual iodine solution.

The next step in the process is the *conversion system,* which includes a preheater and converter. The preheater is a series of vertical iron U pipes and headers housed in a furnace heated by soft coal to give to the gas an initial temperature of 380° C., this being required for proper catalytic action by the contact mass.

The converter is placed close to the preheater and is a vertical cast iron cylinder 6 ft. in diameter and 8½ ft. high, composed of 5 horizontal sections. Each section contains a wire mesh tray for supporting the contact mass and a baffle to properly spread the gas. The contact mass is anhydrous magnesium sulphate carrying two-tenths of 1 per cent metallic platinum in finely divided condition. A total quantity of 5900 lbs. of mass, which is in coarse granules, is spread on the trays to a depth of 14 to 16 inches, leaving a space of about 6 inches between mass sections. The gas enters the bottom of the converter and leaves at the top pyrometer, tubes being provided to read the gas temperature before entrance and in each section. From the converter the gas passes through 180 feet of iron pipe to the absorber. This pipe is air cooled in order that the temperature of the gas may be sufficiently low for good absorption.

The *absorbing system* consists of a tower absorber, an acid cooling pipe, a weak acid mixer and reservoir, a head tank for strong acid, an acid pump, and collecting tank. The tower is a vertical cast iron cylinder 15½ feet high resting on a cast iron base, the top being covered by a perforated plate from the centre of which rises the exit pipe for waste gases. The tower is lined with acid tile and packed with quartz rock. The gas enters on one side near the bottom. A constant stream of acid is supplied by the pump to the top place, percolates through the mass of quartz and passes out at the bottom of the tower to the cooling pipe. This is a horizontal water cooled U pipe, one leg of which carries an overflow pipe connecting with the pump and the collector. The acid supplied to the top of the tower is kept at a temperature of 70° C. and

has a strength of 99.5 per cent. H_2SO_4 just before it enters the cooler.

The reservoir of this weak acid, the mixer and strong acid head tank are mounted on a platform in the center of the building at a sufficient elevation for the acid to flow by gravity. The reservoir is an open lead-lined box holding 1000 gallons. The mixer is a lead pot provided with lead coils for cooling water and a special mixing pipe designed by one of us (Cheney), in which water and strong acid are brought in contact. The mixing pipe consists of two heavy ¾-inch lead pipes set at an angle of 30 deg. and held together by a heavy lead sheath burned onto a short length of 1½-inch lead pipe. One of the ¾-inch pipes carries strong acid from the head tank, and the other ordinary cold water from the mains. The 1½-in. pipe serves to carry the hot mixture to the pot without spatter. This type has the advantage of minimum repair and mixes about 5000 lb. of 75 per cent acid per hour. The head tank has a capacity of 18,000 lb. of strong acid.

The product of the plant passes through a scale tank and is delivered to the nitric acid plant where in winter weather it is mixed with 2 per cent of nitric acid to prevent freezing. The entire product can be delivered as 99.5 per cent H_2SO_4, but for use in making nitric acid a portion of it is reduced to 94 per cent H_2SO_4.

This being a Government plant, the hours of labor for any one shift of men cannot exceed eight. The plant is run continuously with three shifts, and in addition to the men directly employed in the operation of the plant there is a superintendent, who devotes about half of his time to it.

The successful operation of a contact plant, of course, depends largely upon the efficiency of the contact mass. This efficiency is easily influenced by arsenic in the raw materials. should arseniuretted hydrogen be present in the gas entering the converter, arsenic is deposited on the platinum and is said to "poison" it. The result of "poisoning" is immediately noticeable in the temperature produced by the catalytic action and in the quantity of SO_2 unconverted. Fortunately, this effect may be in part counteracted by raising the temperature of the gases entering the converter, and for this reason hardly any two plants burning pyrites will be found using the same initial temperature. In different plants we have noted temperatures of entrance gas varying from 420 deg. C. to 480 deg. C. The catalytic properties of "poisoned" mass may be improved by sprinkling it with aqua regia and expelling the arsenic by the heat of the converter, or they may be entirely restored by heating the mass in a furnace after sprinkling with aqua regia.

Another factor in conversion is the quantity of SO_2 contained in the gas entering the converter. With pyrites it is customary to use an entrance gas containing not over 5.5 per cent SO_2 with mass in good condition. When "poisoning" has occurred, this percentage must be reduced to obtain good conversion.

In this plant, using Louisiana brimstone for eighteen months, there have been no indications of "poisoning" and the converter has not been opened. The temperature of gas entering the converter is kept constantly at 380 deg. C. and conversions are regularly 95 to 95.5 per cent. This low temperature means a decided saving in coal, and wear and tear on the preheater. During six months the average consumption of coal has been 21.8 lb. per 100 lb. of SO_2 made. The authors believe this to be a figure decidedly less than any Schroeder plant burning pyrites. An entrance gas of 6.5 to 7 per cent SO_2 is regularly used.

During six months under the above conditions, the average make has been a little more than 6 tons of acid a day, and the average yield on sulphur fed to the burner 93.36 per cent. This plant can make a maximum quantity of 8 tons with a yield of 90 per cent. Comparison of cost sheets shows that by changing raw materials from pyrites to brimstone, the cost of manufacture has been reduced nearly two dollars per ton of 98 per cent acid; that this reduction is due in part to minimizing losses from shutdowns for repairs, in part to increased yields, and in part to saving in coal and upkeep.

American Sulphuric Acid Industry.

A review of the sulphuric acid industry in the United States is given in a paper by **Utley Wedge,** of Ardmore, Pa.

This is the consumption of sulphuric acid in different industries, the figures being given in terms of tons of 50 deg. Be sulphuric acid per year:

Manufacture of fertilizer	2,400,000 tons
Refining of petroleum products	300,000 tons
Used in iron and steel and coke industry	200,000 tons
Manufacture of nitrocellulose, nitroglycerine, celluloid, etc.	150,000 tons
Manufacture of aluminium sulphate and the different alums, sulphates of magnesium and similar salts, carbon dioxide and hydrogen, sulphide gas, anilin and other organic dies and colors, hydrochloric, nitric, hydrofluoric, chromic, boracic, acetic, picric, and other acids, ether, glucose, blue vitriol, zinc sulphates, and in the metallurgy of copper, gold and silver and general chemical practice	200,000 tons
Total	3,250,000 tons

In the manufacture of phosphatic fertilizer, phosphate rock is treated with sulphuric acid to render the phosphoric acid soluble. One ton of rock phosphate requires treatment with about one ton of 50 deg. Be sulphuric acid.

In refining petroleum products, sulphuric acid 66 deg. Be and sometimes fuming acid is used for the removal of tarry matter, and to some extent sulphur compounds. For example, 1000 barrels of illuminating oil requires for its refining about 2 tons of oil of vitriol.

In the iron and steel industry, very dilute sulphuric acid, free from arsenic, is used for cleansing steel plates or wire preliminary to galvanizing, making copper as a by-product; also the steel companies have gone extensively into the production of coke with by-product coke-ovens, one of the products of which is sulphate of ammonia, which requires a little over a long ton of 50 deg. Be sulphuric acid for each net ton of sulphate of ammonia produced.

In the manufacture of nitrocellulose, nitroglycerine, etc., highly concentrated or contact sulphuric acid is used in connection with strong nitric acid to absorb water formed during nitration which would otherwise interfere with the chemical action desired.

In the manufacture of alum, either bauxite or white alumina, are treated with 50 deg. Be sulphuric acid, free from arsenic, to form aluminium sulphate.

In the manufacture of sulphate of ammonia, ammonia gas is absorbed in scrubbing towers by dilute sulphuric acid or solutions of ammonia are treated direct with sulphuric acid.

In the manufacture of blue vitriol, metallic copper is dissolved by hot sulphuric acid, very dilute. Dilute sulphuric acid is also used to some extent in leaching copper ores, concentrates, or slimes for the recovery of copper values.

Phosphate rock deposits are shown in Florida, Tennessee and South Carolina. There are also deposits of phosphate rock in Utah and elsewhere in the Western States which will have great industrial importance as soon as the demand for phosphatic fertilizer in the West has grown to a point to justify the erection of fertilizer plants.

The composition of commercial fertilizer is usually about one-third sulphuric acid, one-third phosphate rock and one-third other components, chiefly filler, with varying amounts of nitrogenous material and potash salts.

The location of fertilizer plants is decided by the following facts

The phosphate rock has, in any event, either acidulated or not acidulated, to be transported from phosphate deposit to agricultural district where it will be consumed. Filler can be added near the point where the fertilizer will be used. Therefore, the determining factor in the location of phosphatic fertilizer works is the freight on sulphuric acid or crude materials from which it is manufactured

One ton of pyrites containing 50 per cent sulphur will produce 2.35 tons of 50 deg. Be sulphuric acid, so that it is cheaper to transport iron pyrites than to transport the quantity of 50 deg. Be sulphuric acid which a given amount of iron pyrites would produce.

Sulphuric acid plants in connection with fertilizer plants are therefore generally located adjacent to the agricultural districts where the fertilizer will be consumed and not near the deposit of phosphate rock, and combined sulphuric acid and fertilizer plants located near phosphate rock deposits are there merely to supply agricultural requirements in that vicinity. Combined sulphuric acid and fertilizer works are therefore located in parts of the United States where phosphatic fertilizer is required.

Fertilizer is extensively used in connection with the growing of cotton, and the Southern States denoted as cotton growing states, contain very numerous sulphuric acid plants.

In the Northern and Eastern States, the use of phosphatic fertilizer is not nearly so extensive and a less number of combined sulphuric acid and fertilizer plants supply the demand.

The consumption of fertilizer other than in the Western States, is growing so enormously that a most unusual business situation is developing, and even in Utah, combined sulphuric acid and fertilizer plants are now contemplated.

Much the greater portion of sulphuric acid produced in the United States is made from iron pyrites. There were supplied pyrites, in 1911, from Spain 815,000 net tons, from Portugal 133,000 net tons, from the United States and Canada about 350,000 net tons, or a total of 1,298,000 net tons of pyrites. Of this amount 584,000 net tons were delivered to plants in the South manufacturing sulphuric acid exclusively for the production of fertilizer and 236,000 net tons was delivered to plants in the North manufacturing sulphuric acid exclusively for the production of fertilizer.

These quantities of pyrites would represent a production of sulphuric acid in the fertilizer plants in the Southern States of about 1,300,000 tons of 50 deg. Be sulphuric acid, to which should be added 275,000 tons of 50 deg. Be sulphuric acid produced as a by-product by the copper smelters in Tennessee, practically all of which is consumed in the manufacture of fertilizer in the Southern States.

The 236,000 tons of pyrites delivered to plants in the Northern States manufacturing sulphuric acid exclusively for the production of fertilizer, would represent 529,000 tons of 50 deg. Be sulphuric acid.

In addition to the above fertilizer-acid, considerable quantities of sulphuric acid are manufactured in works doing a general chemical business and shipped to fertilizer works for treatment of phosphate rock, also sulphuric acid separated from sludge acid from petroleum refineries, is shipped in considerable quantities to fertilizer works, bringing the consumption of sulphuric acid in the fertilizer business up to the total figures given above.

In the petroleum industry the consumption of sulphuric acid has increased slowly for some years, for the reason that the oil refiners have learned to economize in sulphuric acid and have decreased the quantity used per barrel in refining to largely offset the large increase in the production of petroleum products. For example, previous to 1888 in many oil refineries sulphuric acid was mixed and stirred with distillate only once, being then at once diluted and separated from the combined tarry matter and again concentrated to 66 deg. Be before using again in the oil refining process.

In 1890 the practice came into general use of using sulphuric acid a second time, taking the acid from a previous treatment of distillate and using the partially exhausted acid on a second batch of distillate before separating and concentrating. This materially reduced the consumption of fresh acid. Again, about the year 1896, the use of fullers earth was introduced in oil refining practice. Tarry matter was removed from distillate by agitation with fullers earth and a decreased amount of work remained to be done by sulphuric acid treatment. These two improvements made a material reduction in the use of sulphuric acid in oil refining. Subsequent improvements in method and practice in recovering sulphuric acid from sludge or spent acid have further reduced the net consumption of fresh sulphuric acid by the petroleum industry.

The location of acid plants supplying oil refineries is quite uniformly adjacent to the oil refineries on account of the transportation problem.

Transportation of crude oil by pipe line is so much cheaper than the transportation of refined products by rail, that oil refineries under conditions in the United States are located with reference to transportation and distribution of the refined product and seldom adjacent to oil producing fields, except only to supply the demand for the finished product in the radius of economic shipment from the oil fields. The great oil refineries are therefore chiefly located where there is both rail and water transportation. The map shows oil fields in Pennsylvania, Ohio, Indiana, West Virginia, Indian Territory, Texas, California, and some other states.

The large oil refineries, however, are located along the Atlantic seaboard on the water front near New York Harbor, Philadelphia and Baltimore; along the great lakes at Buffalo, Cleveland and near Chicago; on the Pacific Coast on San Francisco Bay. Minor oil refineries are located near the oil fields.

In every case sulphuric acid plants are located near the oil refineries. The groups near New York are supplied from a large chamber process sulphuric acid plant on New York Harbor, operated by the petroleum refining interest, with an output of about 60,000 tons of oil of vitriol per annum. Oil refineries at Philadelphia and Baltimore are supplied with oil of vitriol from a sulphuric acid plant at Philadelphia, delivering about 40,000 tons of oil of vitriol per annum. The California crude oil requires treatment in part with an acid stronger than oil of vitriol, which is supplied from an oxide-of-iron-contact plant at the oil refinery, on San Francisco Bay.

One small oil refinery adjacent to the Texas oil fields burns brimstone from the Louisiana sulphur deposit.

In many cases the oil refineries or chemical companies supplying them with sulphuric acid are equipped with appliances for separating sulphuric acid from the tarry matter taken up in the treatment of petroleum distillates and the separated acid of 35° Be to 50° Be is then again concentrated to 66° Be for further use. This repeated restoring of the spent acid greatly diminishes the amount of fresh sulphuric acid required by the petroleum industry and brings their net requirements down to the figure given above.

Mention is also made of a practice by the petroleum refiners to a very limited extent of manufacturing sulphuric acid from sulphuretted hydrogen and sulphur dioxide fumes given off during the distillation of petroleum high in sulphur contents. In general the fresh sulphuric acid consumption by the petroleum refining companies represents chiefly the actual decomposition of a percentage of the sulphuric acid used by reduction to SO_2 by the carbon in the oil treated, plus deliveries of separated sulphuric acid 50° Be gravity to fertilizer plants. In addition to the mechanical loss in use, there is actual decomposition to SO_2 during treatment, especially of heavy oils, and also the decomposition is considerable in the process of separating and reconcentrating the sulphuric acid.

Counting the repeated use of sulphuric acid by the petroleum industry, their actual use of oil of vitriol would be about 334,000 tons per annum, representing 500,000 tons of 50° Be equivalent.

The iron and steel industry uses such considerable amounts of sulphuric acid that a tendency is developing for steel companies to erect and operate their separate sulphuric acid plants.

The manufacture of sulphate of ammonia from by-product coke-ovens has been taken up by the steel companies.

A coke plant consuming 2000 tons of coal per day would produce from 14 to 30 tons of sulphate of ammonia daily, according to the nitrogen content of the coal used. Therefore, each 2000 tons of coal, high in nitrogen, converted into coke daily, would call for a sulphuric acid production of 10,000 tons of 50° Be sulphuric acid per year.

The location of sulphuric acid plants to supply this demand has so far been adjacent to the steel plants in Pennsylvania, Indiana, Michigan and Alabama.

By-product coke-ovens are now constructing or under consideration which will require 100,000 to 150,000 tons of 50° Be sulphuric acid per annum, in addition to the figure shown above.

This development has so far been chiefly in connection with the iron and steel industry.

One of the sulphuric acid plants operated by one of the steel companies burns brimstone from Louisiana; the others burn pyrites.

All the acid plants so far constructed have been chamber-plants, although one by-product plant now constructing has contracted for its supply of sulphuric acid from a concern producing contact acid.

In the manufacture of nitrocellulose, nitroglycerine and similar products, the chamber process has been practically eliminated by the contact process. Contact processes have been installed wherever these explosives are manufactured. Several iron-oxide contact plants have been erected for this purpose as well as other contact systems.

In the general chemical industry the various platinum and iron contact systems have made considerable progress, more especially where the demand is for sulphuric acid approaching the composition of the monohydrate.

Out of a total production of sulphuric acid in the United States of 3,250,000 net tons per annum, approximately 10 per cent is contact acid made either by the iron-oxide contact or by the platinum contact systems.

Of the Spanish pyrites imported during 1911, namely, 815,000 tons, 37 per cent was copper-bearing pyrites, of which about 200,000 tons were chloridized and leached for the recovery of copper values, after burning off the sulphur for the manufacture of sulphuric acid.

Of the 646,000 tons of iron pyrites imported during 1911 containing no copper values, about 230,000 was washed fines from which copper had been leached in Spain or Portugal before shipment to this country.

The practice of nodulizing cinder from pyrites burners has become general in all localities where there is a market for the nodulized cinder as iron ore. The iron industry of Pennsylvania furnishes a good market. In Alabama the iron manufacturers have not as yet offered prices for low phosphorus nodulized cinder such as to make profitable the installation of nodulizing kilns, and there is in the South the accumulated cinder from years of sulphuric acid manufacture, waiting for prices which will make its utilization profitable.

An analysis of the source of sulphuric acid manufactured in the United States during 1911 would show as follows, figures given being expressed in terms of 50° Be sulphuric acid:

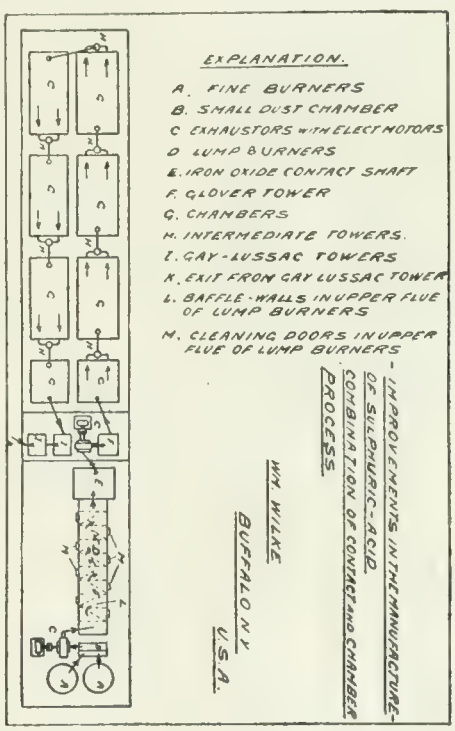
Manufactured from pyrites	2,665,000 tons
Manufactured from blast furnaces, smelting copper sulphide ores	275,000 tons
Manufactured from zinc sulphide ores	285,000 tons
Manufactured from brimstone	25,000 tons
Total	3,250,000 tons

Combination of the Contact Process with the Lead Chamber.

"The Combination of the Contact Process with the Ordinary Lead Chamber or Tower Systems—An Improvement in the Manufacture of Sulphuric Acid," is the title of a paper by **William Wilke**, of Buffalo, N. Y. He describes a system in which the contact process is combined with the chamber system, giving a successful working method that shows decided economies and advantages.

The plant for which the author devised this system had already an installation of the contact process licensed under patents of the Verein Chemischer Fabriken in Mannheim for the production of strong acid, and the question arose whether they could economically and profitably reduce this highly concentrated acid to lower strengths. They found that this was commercially impossible to do. There was, however, a market for chamber acid; consequently it was thought possible to combine the contact process with the chamber process and attain the end in view.

A plant was designed as shown in Fig. 1. In order to be independent of the constant variations in the pyrites market and the possible scarcity of pyrite fines, the plant was so designed that lump ore as well as fines could be roasted,



EXPLANATION.

FIG. 1.—IMPROVED PROCESS FOR MANUFACTURE OF SULPHURIC ACID.

the burning capacity finally adopted being 24,000 lbs. fines and 36,000 lump ore. Thirty-six lump burners were installed, each able to handle from 900 to 1200 lbs. ore daily, and four standard Herreshoff fines burners.

The gases from the fines burners were conducted into a flue situated above the flue of the lump burners and provided with a number of baffle walls to catch some of the dust. The gases of the lump burners and fines burners were united and conducted into the patented iron-oxide-contact-shaft, similar to the contact process chamber of the Verein Chemischer Fabriken. In order to regulate the draft on the fines burners, a separate exhaust fan was installed to draw the gases from the fines burners and deliver them into the flue over the lump burners. A second exhaust fan was installed between the iron-oxide-contact-shaft and the Glover tower, which took the sulphurous gases after they had undergone conversion, to the extent of 30 per cent, into SO_3 by the iron-oxide contact-

shaft and forced them through the Glover tower into the chamber system.

The combination of the two very distinct processes into one system gave most excellent results. The capacity of the chamber plant was increased at least 30 per cent. The conversion of SO_2 to SO_3 in the iron-oxide-contact-shaft averaged about 30 per cent. At the same time the acid produced in the Glover tower was water white. Ninety-five per cent of the arsenic carried by the gases leaving the roasters and flues was eliminated by means of the iron-oxide, and, finally, it was found that the total production of the chamber system could easily be concentrated to 60 deg. Baume or higher in the Glover tower.

Such satisfactory results are all attributable to the introduction of the iron-oxide-contact-shaft between the burners and the Glover tower; in other words, to the suitable combination of the contact and the lead chamber processes

The iron-oxide-contact-shaft retards the dust and is the best known means of keeping dust from getting into the chamber system; it is an accumulator of heat and acts as an equalizer on any system, such as that described, enabling the operator of the plant to carry out the process more uniformly; it saves 30 per cent of the nitre consumed in the ordinary plant, on account of the conversion by the catalytic action.

Since constructing the above described plant, the iron-oxide-contact-shaft has been introduced in other existing chamber plants with equally good results.

In the absence of Dr. Hart, the following paper was read by title:

Potash, Silica and Alumina from Feldspar.—A paper by **Edward Hart,** of Lafayette College, points out that the potash alone would not pay the cost of extraction from feldspar. It is necessary, therefore, to separate and put into marketable form the other constituents—silica and alumina—if the method is to be successful.

The feldspar chosen should contain not much less than 12 per cent potash. The spar mixed with the proper amount of potassium sulphate and carbon is fused. The carbon added is so regulated that the resulting slag contains a considerable proportion of sulphides. This has the double advantage of saving a part of the sulphur, disengaged as hydrogen sulphide on dissolving in acids, which aids also in the complete decomposition by breaking apart the particles as it is given off. Experiments show that if a colorless slag is obtained of even higher alkali content it is much less easily decomposed by sulphuric acid. The slag so obtained must be very finely pulverized and treated in closed vessels with dilute sulphuric acid, leaving behind a very pure silica which only needs washing and ignition to yield a marketable product fitted for the potter's use or for the manufacture of sodium silicate.

The solution contains potash alum and many small amounts of other metals such as iron, manganese, and soda as sulphates. Lime is inadmissible, as the sulphate forms crusts on evaporating.

The solution on cooling gives at once crystals of alum, which washing with a little water and centrifuging renders marketable. Any iron present remains as ferrous sulphate in the mother liquor. Alum, however, is marketable only in limited quantity and must be for the most part converted into its constituents, aluminium and potassium sulphates. This is easily done by adding to the solution in a closed vessel potassium sulphide in slight excess when aluminium hydroxid mixed with a little sulphur precipitates in a form easily washed. This is dissolved in hot sulphuric acid, run through a filter and allowed to solidify.. The potassium sulphate is obtained by evaporation.

Each ton of feldspar (12% K_2O) should yield—

444 lbs. K_2SO_4.

2040 lbs. commercial aluminium sulphate (18% Al_2O_3).

1300 lbs. SiO_2.

In the absence of the author, **Dr. Charles Baskerville,** the following paper was read by title:

Extraction of Thoria.—A new process for the extraction of thoria is the subject of a paper by **Charles Baskerville** of the College of the City of New York. Thorium dioxide is obtained in the main from monazite sands, which, in round numbers, may be said to have this composition:

P_2O_5 (phosphates)	29 per cent.
Ce_2O_3 (earths)	31 per cent.
Di_2O_3 (earths)	31 per cent.
SiO_2 (silicates)	1.50 per cent.
ThO_2 (silicates and perhaps phosphates)	6.50 per cent.

A special feature of the author's new process is the deliberate production of calcium carbide. He makes up the charge as follows:

Monazite sand	1.0 lb.
Carbon (petroleum coke)	1.10 lb.
Lime	0.80 lb.
Fluorspar	0.15 lb.

This charge was treated in an electric furnace consuming 125 amp. at 35 volts for one and a half hours. Unground monazite sand is being used. The charge is subjected to electric heat until phosphorus ceases to come off. The mass is allowed to cool and then to decompose slowly by exposure to the air or quickly by placing in water. In the latter case the acetylene may be utilized, the mass falling to a fine powder. The dissolved and suspended calcium hydroxide are removed by washing. The residue is treated with hydrochloric acid and the thorium separated from the solution by sodium thiosulphate or other methods. The process is controlled by the Welsbach Light Company of Gloucester City, N. J.

Phosphorus and Its Compounds; Studied Especially in Relation to the Manufacture of Matches. A paper by **E. G. Clayton,** of London, England, discussing the desirable conditions in match manufacture. In the discussion of this paper, **Mr. Jerome Alexander** said:

"I think it should appear on the records of this Congress that last year the Diamond Match Company, one of the largest manufacturers of matches in the world, voluntarily surrendered for cancellation its American patents for the use of the non-poisonous sesquisulphide of phosphorus in the manufacture of matches, and at the same time gave out a practical formula for using it, so that this material is now available to all of its competitors.

"Such public-spirited action on behalf of a large corporation in thus deliberately relinquishing valuable patents is particularly praiseworthy, and shows that although corporations are supposed to be soulless, here is a corporation with a soul and officers who consider the public welfare as well as dividends.

"It was this action of the Diamond Match Company that made possible the passage by the United States Congress of the Hughes-Esch bill during March, 1912, which lays such a prohibitive tax on the manufacture of poisonous white phosphorus matches that none of them will be made in this country after July 1, 1913."

In the afternoon a meeting was held in the Doremus Lecture Theatre at the College of the City of New York, where the following program had been arranged:

The Production of Chlorine Substitution Products of Methane from Natural Gas. By **Charles Baskerville** and **H. S. Riederer.**

Notes on Fluorescence and Phosphorescence. By **W. S. Andrews.**

Chemiluminescence. By **Wilder D. Bancroft.**

Color Photography of Luminescence. By **E. F. Farnau** and **J. M. Lohr.**

Blue Gelatine-Copper.—A paper by **Wilder D. Bancroft** and **T. R. Briggs,** of Cornell University, describes an investigation in which the electrolytic production of a form of

colloidal copper was performed with certain copper solutions containing gelatine.

This new form of copper develops a remarkable series of colors when immersed in certain copper solutions, a peacock blue being the finest color obtained.

The process of development is an absorption of hydrous copper oxide by the surface of the colloid film. Methods of coloring metal objects gold, golden brown or red are described.

Joint Meeting of Sections on Analytical Chemistry and Fuels and Asphalt

The first business on the program at this meeting was a consideration of the report of the sub-committee on standardization of methods of determining water in coal and in other fuels and minerals, which was presented by **Geo. T. Holloway.**

The following papers were then presented by the authors or their representatives:

Errors in the Determination of Moisture in Coal. By **W. E. Hillebrand** and **W. L. Badger.**

Influence de la grosseur du grain dans l'analyse des charbons. By **C. Nicolardot.**

A New Bomb Calorimeter, With Special Advantages as to Material of Construction and Method of Operation. By **S. W. Parr.**

Some Tests on a New Calorimeter Bomb. By **R. H. Jesse, Jr.**

Determination of Sulphur in Oils.—A paper by **Irving C. Allen** and **T. W. Robertson,** of the Bureau of Mines, Pittsburgh, Pa., discusses critically eight different methods. The first three methods are:

1. Dry fusion with alkalies and subsequent oxidations with bromine.

2. Dry fusion with a mixture of alkalies and oxidizing agents.

3. Treating with wet alkalies and oxidizing agents.

These three methods, though successful with such slow-burning materials as coals and cokes, are not dependable with oils.

4. Oxidation with fuming nitric acid at high pressures is accurate, but because of frequent explosions is unsatisfactory.

5. Burning in pure oxygen at atmospheric pressure is not accurate because at atmospheric pressure the combustion is not always complete.

6. Burning in a stream of pure oxygen is accurate, but is tedious and must be under the constant observation of the operator.

7. Burning in a lamp in atmospheric oxygen is applicable to burning oils, but not to gaseous oils or to heavy residues.

8. Burning in a calorimetric bomb under 30 to 40 atmospheres pressure of pure oxygen is applicable to all oils and combustible materials, and is accurate, rapid, and dependable.

Determination of Water in Petroleum.—A paper by **Irving C. Allen** and **Walter A. Jacobs,** of the U. S. Bureau of Mines, Pittsburgh, Pa., discusses critically ten different methods for the determination of water in petroleum and its products.

1. The method based on the determination of the loss in weight on heating is approximate and applicable to heavy oils and greases only.

2. Diluting with a solvent and settling by gravity is approximate and applicable to thin oils. A diluent is to be avoided.

3. Diluting with a solvent and separating with a centrifuge is like method 2, but more rapid.

4. Treating with calcium carbide is convenient and, with petroleums, accurate to approximately 3 per cent of the water percentage.

5. Treating with sodium is convenient and accurate.

6. The use of a color comparitor tube is approximate only

7. Treating with normal acids is approximate only.

8. Electrical treatment with a high-tension current is successful in breaking up an emulsion on a commercial scale or in reducing the water content of an oil to such a condition that it can be successfully treated in some other manner.

9. Distilling with a non-miscible liquid is accurate to approximately 0.033 gram of water per 100 cc of benzine and oil in the distillate.

10. Directly distilling off the water is convenient and can be used simultaneously with a distillation. It is accurate to about 0.003 gram of water in the distillate if the water be cooled to about 2 deg. C.

In addition to these papers Mr. **Pontus H. Conradson** presented the following papers in abstract:

Apparatus for the Examination and Study of the Behavior of Valve and Cylinder Oils, and Other Petroleum Lubricating Oils in Saturated and Superheated Steam, Carbon Dioxide, Air and Other Gases.

Apparatus and Method for Sulphur Determination in Petroleum Illuminating and Lubricating Oils.

Apparatus and Method for Carbon Test and Ash Residue in Petroleum Lubricating Oils.

Section on Explosives

At the Tuesday morning session of this section there were three papers read.

Effect of Nitrotoluenes on Determinations of Nitroglycerin by the Nitrometer. By **C. G. Storm.**

Boiling Points of Solutions of Nitroglycerin. By **A. L. Hyde.**

Separation of Nitroglycerin from Nitrosubstitution Compounds. By **A. L. Hyde.**

Section on Organic Chemistry

A long program had been arranged for the Tuesday meetings of this section, but owing to the absence of many of the authors there were but a few papers read. The first was on

The Rennin Coagulation of Milk from a Colloid Chemical Standpoint. By **J. Alexander,** which was followed by

The Copper Salts of Amino Acids, Peptides and Peptones. By **P. A. Kober** and **K. Sugiura.**

Phenolphthalein and Its Colorless Salts. By **P. A. Kober, J. T. Marshall** and **E. N. Rosenfeld.**

The meeting closed with a paper brought forward from Monday on

Researches on Pyrimidines: The Catalytic Action of Esters in the Claisen Condensation. By **T. B. Johnson** and **A. J. Hill.**

Section on Industry and Chemistry of Sugar

On Tuesday this section held a joint session with the International Commission for Uniform Methods of Sugar Analysis to consider the work of the commission since its last meeting in London May 31, 1909. The following reports were considered:

Einheitliche Methoden der Zuckerbestimmung in den Rohmaterialien der Zuckerfabrikation.

Einheitliche Methoden zur Bestimmung des spezifischen Gewichtes von Zuckerlosungen. Referenten Herr Saillard, Paris; **Herr von Buchka,** Berlin.

Beschlussfassung uber eine Nachprufung der Inversionskonstanten fur die Clerget-Herzfeld'sche Methode.

Section on Paints, Drying Oils and Varnishes

At the Tuesday meetings of this section **John R. MacPherson Klatz** presented a paper on

Benzol, Toluol and the Naphthas from Coal Tar as Paint Materials. A Summary of the Possibilities of Each Grade Offered.

This was followed by **Edwin F. Hicks,** who discussed **Shellac Analysis and the Detection of Small Amounts of Colophony in Shellac.**

In the afternoon the following program was carried out as announced:

The Examination of the Oleoresins from Several Species of Pine Natives to the Western States. By **A. W. Schorger.**

Herring Oil. By **A. Lusskin.**

The Manufacture and Properties of Sublimed White Lead. By **J. A. Schaeffer.**

Section on Starch, Cellulose and Paper

At the Tuesday meetings of this section the following papers were presented by their authors:

Dextrine, ihre Fabrikation und Verrendung. By **Edmund Parrow.**

Modified Starches, Their Properties and Manufacture. By **Bernard Herstein.**

Some Special Aspects of Starch. By **Chester B. Duryea.**

A Study of Some of the Physical Properties of Starches. By **Hambden Buel.**

Notes on the Hydrolysis of Starch by Acids. By **George Defren.**

The Presence of Maltose in Acid Converted Starch Products. By **George Defren.**

Section on Fermentation

The Tuesday program for this section was adhered to as originally announced. The following papers were presented by the authors or their representatives:

The Bacillus Viscosus and Its Action on American Ale and Beer Worts, Before, During and After Their Alcoholic Fermentation. By **H. Winther.**

Relation of the Reducing Power to the Fermentation Capacity of the Various Carbohydrates. By **Emil Schlichting.**

Metal Turbidities. By **Gustave Goob.**

Brewing Water. By **W. Windisch.**

Sources of Error in the Determination of the Acidity in Wort and Beer. By **E. Stuhlmann.**

The Composition of Brewers' Extract, from the Standpoints of Chemistry and Biology. By **Francis Wyatt.**

Growth and Development of the Bottling Beer Industry of the United States. By **W. L. Straus.**

Section on Agricultural Chemistry

The following is the program for this section as carried out on Tuesday:

Etude Agrologique du Manganese. By **P. Nottin.**

Die Steigerung des Calciumcyanamids auf den Ertrag landwirschaftlicher Kulturpfanzen unter dem Einfluss von Eisen. By **A. Stuzer.**

The Effect of Fertilizers on the Composition of the Asparagus Plant. By **F. W. Morse.**

A Study of the Variations in Chemical Composition of the Timothy and Wheat Plants During Growth and Ripening. By **L. D. Haigh.**

The Fertilizing Effect of Palmaer-Phosphate on Peat Soils. By **Hjalmar Feilitzen.**

Soil Potash and Phosphoric Acid and Their Relation to Pot and Field Experiments. By **G. S. Fraps.**

The Combustible Gases Excreted by Cattle. By **J. A. Fries.**

The Composition of Beef Fat as Influenced by the Age and Condition of the Animal and Location in the Body. By **E. Morgan.**

Section on Pharmaceutical Chemistry

At the Tuesday morning session of this section the following program was announced:

Solubility and Distribution Coefficients of Thymol. By **Atherton Seidell.**

Arsenites of Alkaloids. By **A. C. Mangold.**

Section on Bromatology

The program carried out in this section on Tuesday [illegible] as follows:

Culture and Manufacture of Morel—Armenian Cherry—in Dalmatia. By **E. Nicolic.**

On the Chemical Composition of "Salzbreies" of Bonito ("Shiokara").—A paper in German by **U. Suzuki, C. Yoneyama** and **S. Odake,** of the Agricultural College, Imperial University, Tokyo, Japan.

On the Antiseptic Character of Sea Salt and Sugar.—A paper in French by **M. L. Lindet,** of Paris, France.

Permanent Fireproofing of Cotton Goods

An Address by the Representative of Great Britain.

On Tuesday afternoon Dr. **William Henry Perkin,** of Manchester, England (the son of the distinguished late Sir William Perkin, who invented mauve and thus became the founder of the coal tar industry), delivered the general lecture at the Doremus Lecture Theatre in the College of the City of New York, as the representative of Great Britain. While he has been very much interested actively in the synthesis of rubber, he did not discuss this subject, as it had been written up by Dr. Dinsburg. For this reason Dr. Perkin had selected another subject on which he had done much work, namely, the permanent fireproofing of cotton goods. By permanent fireproofing he means protection which is not removed when the materials are subjected to the ordinary domestic wash.

Permanent Fireproofing

That this is a very important point can be seen from the following considerations:

Rinsing a garment after washing it in the ordinary way in a solution containing alum or starching it with a starch containing a proportion of alum makes it fireproof, but the fireproofing is only temporary because when the garment is washed the protecting salt is washed out. It is, therefore, clear that to get permanent fireproofing the fireproofing agent must not be soluble in water.

Dr. Perkin described a long series of experiments which he made in connection with the fireproofing of flannelette, following the lines of thought given above:

Many unsuccessful attempts were made, but finally the following successful process was worked out. The flannelette (or other material) is run through a solution of sodium stannate of approximately 45° Tw. in such a manner that it becomes thoroughly impregnated. It is then squeezed to remove the excess of the solution, passed over heated copper drums in order to thoroughly dry it, after which it is run through a solution of ammonium sulphate of about 15° Tw. and again squeezed and dried. Apart from the precipitated stannic oxide, the material now contains sodium sulphate and this is removed by passage through water; the material is then dried and subjected to the ordinary processes of finishing.

Stannic Oxide Process

A long series of trials, carried out under the most stringent conditions, have conclusively proved that material, subjected to this process, is permanently fireproofed. No amount of washing with hot soap and water will remove the fireproofing agent, or in other words, the property of resisting flame lasts so long as the material itself lasts. This was demonstrated by exhibiting four different specimens; (i) material as it leaves the process and before washing, (ii) material which has been washed ten times by hand, (iii) material washed twenty times in a machine in a laundry and (iv) a portion of a garment which has been in actual use for two years, washed every week and is, as you see, in rags.

This extraordinary property of resisting soap and water seems to indicate that the oxide of tin is not present merely as an insoluble precipitate in the cloth but must have entered into some actual combination with the fibre, yielding a compound which is not broken down by the action of the weak alkali of the soap. But a matter of hardly less importance from the practical point of view is that the material is not only permanently fireproofed by the process just described; it also retains and acquires properties which make it as perfect a material in all other respects as could be desired.

Combination of Fibre with Precipitate

In the first place the treatment has no effect on the delicate colors which are now so generally employed in connection with the manufacture of flannelette and other cotton goods and very careful experiments have demonstrated the fact that the insoluble tin compound in the fibre has not the slightest deleterious action on the most delicate skin. In addition, the presence of the tin compound in the pores gives the cloth a softer and fuller feel than that of the original flannelette and what perhaps is the most unexpected result is the fact that the material is considerably strengthened by the process.

A series of tests made by the Manchester Chamber of Commerce proved that the tensile strength of flannelette is increased nearly 20 per cent as the result of the introduction of the tin compound into the fibre.

Further and very exhaustive tests made at the Municipal School of Technology, Manchester, on a machine specially designed for testing the wearing properties of fabrics, showed an even greater gain in durability in the case of the fireproofed flannelette. These separate and independent tests conclusively showed that the increase in strength and durability was approximately equal to the cost of the fireproofing treatment so that garments made from the permanently fireproofed flannelette are as a matter of fact no dearer than those made from ordinary flannelette and are at the same time as safe as if made from flannel.

This permanently fireproofed flannelette is now manufactured on the large scale by Whipp Bros. and Tod in Manchester under the name of Non-Flam and, although its introduction has been slow, it is being increasingly used and will, in all probability, ultimately entirely replace the ordinary inflammable variety. One of the difficulties experienced in connection with its general introduction is the fact that, owing to the high price of tin, which is now quoted at about £210 or $1050 per ton, the cost of the process is not inconsiderable but, even with tin at this high price, the extra cost is not more than 1d. (2 cents) per yard or about 1½d or 2d. (3 to 4 cents) for a child's garment.

During the lecture the Honorary President of the Congress, Dr. Morley, presided. Dr. C. F. Chandler offered a vote of thanks to the speaker, and Dr. F. W. Clark, Washington, D. C., seconded the motion. The lecture was illustrated in a very interesting way by several demonstrations of the non-inflammability of materials treated by the process described.

Reception at the Chemists' Club

The Chemists' Club tendered a reception to the members of the Congress, their wives, and friends on Tuesday evening, September 10. The president and trustees of the Club received the guests in the club parlor. Among those in the receiving line were Dr. and Mrs. Loeb, Dr. and Mrs. Moore, Dr. and Mrs. Teeple, Dr. Geo. F. Kunz, Mr. W. S. Gray, Mr. Ellwood Hendrick, Mr. and Mrs. William James Evans, and Dr. E. G. Love. Over a thousand guests attended the reception.

The club parlors, dining room and roof garden were very prettily decorated. During the evening music was rendered by the Chemists' Club quartette. A collation was served in the dining room and on the roof garden.

During the evening the guests witnessed an exhibition of moving pictures of Paul J. Rainey's African Hunt, which was given in Rumford Hall.

The Club library and the laboratories in the building were open for inspection during the evening.

Wednesday Meetings of Congress Sections

General Lecture by H. A. Bernthsen on Synthetic Ammonia—General Lecture by Giacomo Ciamician on Photochemistry—Symposium on Corrosion—Synthetic Rubber—Artificial Production of Coal

Synthetic Ammonia Realized

The Haber Process in the Hands of the Badische Company.

One of the most important lectures with respect to novelty was that of Geheimrat Dr. **H. A. Bernthsen** presented before a joint meeting of Sections II, VII, Xa and Xb at the Horace Man Auditorium on synthetic ammonia.

Dr. Bernthsen referred to the complete indifference of nitrogen to chemical attack under ordinary conditions. This is the reason why although we live in an infinite ocean of nitrogen, yet up to a short time ago we were not in a position to obtain nitrogen compounds from it. But now long extended and systematic research has changed the situation. The three methods now employed for the fixation of nitrogen are, first, the direct oxidation of nitrogen of the air forming nitric acid, nitrates, etc.; second, the synthesis of ammonia from nitrogen and hydrogen, and, third, the fixation of nitrogen to metals or metalloids and, if desired, subsequently, decomposing the resulting products, nitrids, etc., producing ammonia.

Fixation of Atmospheric Nitrogen

Dr. Bernthsen referred only briefly to the first and the third method and then stated that his paper would deal in detail from his own direct experience, with the development of the second method—the problem for the synthetical manufacture of ammonia from its elements. "A few years ago the solution of this problem appeared to be absolutely impossible. It has recently been the object of very painstaking investigations by Professor Haber and the chemists of the Badische Anilin- und Soda-Fabrik, and numerous patents have been taken out with reference to the manufacture. Apart from what is already published in this way, however, we have refrained from any other announcements until we were in a position to report something final with reference to the solution of the technical question.

Synthetic Ammonia an Accomplished Fact

"This moment has now arrived and I am in the agreeable position of being able to inform you that the said problem has now been solved fully on a manufacturing scale, and that the walls of our first factory for synthetic ammonia are already rising above the ground at Oppau, near Ludwigshafen-on-Rhine."

Dr Bernthsen first gave a brief account of the former researches of various investigators up to the time when Professor Haber became interested in the subject.

The investigations entered upon a new phase when Haber, armed with the weapons of modern physical-chemical methods, attacked the problem of the estimation of the ammonia equilibrium in 1904 in conjunction with van Oordt (*Zeit. f. Anorgan. Chemie*, vol. 43, 111). These investigators showed that at a temperature of about 1000 deg. C. decomposition of ammonia into its elements was almost, but not quite, quantitative (of 1000 molecules of ammonia 999.76 were decomposed at a temperature of 1020 deg. C), and that consequently from these elements and under the same conditions very small quantities of ammonia were formed.

Haber's Work

The authors used as contact material iron prepared from iron oxalate by heating to red heat in a current of hydrogen, and the iron was spread out upon purified asbestos. Further for some experiments nickel was precipitated from nickel nitrate upon pure silica. From a mixture of nitrogen and hydrogen corresponding to 100 parts of ammonia they obtained at the temperature mentioned about 0.02 parts of ammonia, and even this figure was subsequently, by more accurate examination, shown to be still too high. In a further publication in 1905 (*Zeit. f. anorgan. Chemie*, 44, 341) these results were confirmed and summarized in the following sense, namely, at the temperature of commencing red heat and upwards no catalyzer is capable of producing more than traces of ammonia. The work was carried out at ordinary atmospheric pressure "for practical reasons," and it was pointed out that even under considerably increased pressure the position of the equilibrium would remain very unfavorable. Manganese was also taken into consideration as a catalyzer, but its effect, as also that of nickel, was less satisfactory than that of iron.

While Haber in company with Le Rossignol (*Ber.*, 40 (1907), II, 2144) pursued this line of research, Nernst communicated the results of similar investigations to the general meeting of the German Bunsen Gesellschaft at Hamburg in 1907 (*Zeit. f. Elektrochemie*, v. 13 (1907), p. 521). He was induced to take the matter up by the fact that Haber's figures showed a remarkable discrepancy from the equilibrium figures calculated according to the famous "heat theorem" of Nernst himself. In order to determine the otherwise so minute quantities of ammonia Nernst worked under pressure, using as a rule about 50 and up to 75 atmospheres, for, according to the well-known laws, the concentration of the ammonia increases with the pressure.

These results were published more in detail a year later by his co-worker Jost (*Zeit. f. anorgan. Chemie.*, 57, p. 414). The latter used as catalysts besides platinum foil or iron (prepared from iron oxide in a current of hydrogen), also manganese (obtained from an electrically prepared amalgam by driving off the mercury in a current of ammonia). The figures here obtained for the equilibrium were still lower than Haber's, a fact which Nernst said was very regrettable, for otherwise one might really have thought of preparing ammonia synthetically from hydrogen and nitrogen.

Haber and Le Rossignol made a further publication in 1908, (*Zeit. f. Elektrochemie*, v. 14 (1908), p. 181), having now made their measurements also at a pressure of 30 atmospheres. By this means, it is true, the differences as against Nernst's experiments on account of the position of equilibrium, as also the maximum percentage of ammonia obtainable at a given temperature, were not quite got over, but at all events the figures of both scientists agreed in showing that this maximum is extremely low. At a temperature of 1000 deg. C. the volume percentage of ammonia calculated for atmospheric pressure is 0.0048 per cent according to Haber and 0.0032 per cent according to Jost, the corresponding figures at 700 deg. C. being 0.0221 per cent and 0.0174 per cent. That is, at these temperatures the ammonia equilibrium is extremely unfavorable, whilst at lower temperatures the catalytic action of the metals in question was too low.

Haber-Nernst Controversy

To sum up all these investigations on the direct combination of nitrogen and ammonia, it can be said that the problem seemed now to have become more than ever a mere dream, of which the realization appeared to be quite beyond the bounds of possibility, so that there was every reason why the scientist should turn his back on so unfruitful a field.

In spite of this, Haber had a feeling that a technical synthesis of ammonia from its elements could be rendered possible, and placed himself in communication with the Badische Anilin- & Soda-Fabrik for the promotion of the work. He then showed, still in 1908 (German patent 235,421 of October 13, 1908), that the technical preparation of ammonia from its elements can in fact be carried out, in spite of the unfavorable equilibrium and the low catalytic capacity of the contact metals used, if the mixture of nitrogen and hydrogen is kept under constant pressure during the whole of the operation and is subjected alternately to the catalytic formation of ammonia at a high temperature and then freed from ammonia by absorption or condensation at a lower temperature.

Care must at the same time be taken that the heat of the reaction gases containing ammonia is transferred afresh to the gas mixture about to be acted on. In other words, the nitrogen-hydrogen mixture circulates, under continuous pressure, through the vessel for the formation of the ammonia, the vessel for the separation of the ammonia and a circulating pump, all these being connected up to a closed endless circuit. Of course it is advisable at the same time to replace with a fresh nitrogen-hydrogen mixture so much of the gas as is converted into ammonia.

PHOTOGRAPH TAKEN AT SOMMERS OF THE VEREIN DEUTS HER CHEMIKER

It was further found when working according to this continuous process of Haber's under conditions which induce a relatively high concentration of ammonia that the advantages of the heat regeneration are no longer of such vital importance, but that it is sufficient in this case to work continuously under pressure without at the same time regenerating heat (French patent 406,943). Finally, it was seen (German patent 238,450 of Sept. 14, 1909), that it is not even absolutely necessary to work continuously under pressure (that is, to circulate the gases continuously under pressure), if the reaction is carried out under very high pressure, for instance at about 100 atmospheres, preferably however at from 150 to 250 atmospheres and even higher. A range of pressure is hereby introduced which had never been touched in the synthesis of ammonia and was also something quite new in any manufacture, for no one had previously so much as thought of carrying out technically a catalytic reaction with gas currents at the necessary high temperatures under such an enormous pressure.

Further Research by Haber

By these means, under a pressure of 200 atmospheres, at a temperature of from 650 to 700 deg. C. and using an iron catalyst prepared from the purest iron oxide, occupying a space of 20 ccm, and with a gas speed of 250 liters per hour (measured at ordinary pressure) it is an easy matter to obtain for example 5 grams, or per liter of contact space 250 grams, of ammonia in an hour.

The following further point comes here into consideration. All previous publications had in view exclusively the determination of the ammonia equilibrium, which can be found theoretically most accurately in a steady volume of gas. If a current of gas is used, the rate of flow must naturally be kept low, so that one may be sure that equilibrium is reached. Now there were no indications as to how far the concentration of the gas would be reduced when the rate of flow is raised, and whether the concentration would be sufficient when such a rate of flow is taken as must be done when working on a technical scale. Haber has therefore rendered signal service in showing that one can work successfully with such higher rates of flow.

A diagrammatic exposition of an apparatus used by Haber was exhibited by Dr. Bernthun. The catalyst is in a metal tube which opens in front into a heat regenerator. The gas mixture passes from behind into the metal tube[1] through the catalyst and then through the heat regenerator into a circulating pump. Leaving this it passes in countercurrent round the outside of the regenerator tubes and the tube, containing the catalyst and then enters this in front, repeating this journey again as described. The apparatus can be protected against loss of heat to the air by packing it in isolating material and can be enclosed in an outer shell which can withstand the pressure. The whole of the circulation takes place at high pressure. The catalyst is kept at the suitable temperature by electrically heating from within or by applying heat from the outside. Between the heat regenerator and the circulating pump the gases pass through either an absorber or a condenser for ammonia. By means of a branch tube the nitrogen and hydrogen combined to ammonia can be replaced.

Finally, it was a great step forward when Haber found catalysts with the property of rapidly combining nitrogen and hydrogen to ammonia in sufficient quantity even at much lower temperatures than those previously required. He found this to be especially the case with osmium. This metal has such a very favorable action already at 550 deg. C. and below, that under a pressure of 175 atmospheres a gas concentration of 8 volumes per cent of ammonia can be obtained. This was all the more astonishing, as platinum, which is closely related to osmium, has but a very slight catalytic action. For use on a large scale, however, osmium scarcely comes into consideration, for the world's stocks according to Haber do not amount to much over 100 kg and only small quantities are won annually; this quite apart from its high price and very unpleasant properties.

New Catalytic Agents

Very soon Haber found in uranium a further very good catalyst; it can be employed in the form of the metal, of an alloy, or nitrid, or carbid. In the form containing carbon or carbid, such as is produced in the electric arc from uranium oxid and carbon, it crumbles in the gas mixture under high pressure to a very fine powder containing nitrogen, which even under 500 deg. C. has an excellent catalytic action. No water, however, or impurities which give rise to water must be present in the gases, when uranium is used in this way. From the following table, which shows the equilibria obtainable at different temperatures and pressures, can be seen the importance of the temperature at which a catalyst is active for the equilibrium of the ammonia produced.

Equilibria ($N_2 : 3H_2$)

Temp.	pressure 1 atm.	100 atm.
800 deg.	0.011 per cent.	1.1 per cent.
700 "	0.021 " "	2.1 " "
600 "	0.048 " "	4.5 " "
500 "	0.13 " "	10.8 " "
400 "	0.48 " "	

"Haber published a short report of his work in 1910 (*Zeit. f. Elektrochemie*, vol 16, 244/5). To my great regret Professor Haber has not been able to accept the invitation of the officers of this Congress to report personally here on his researches, owing to being hindered by pressure of work. I have great pleasure in fulfilling his wish and thanking the officers of the Congress to-day for the honorable invitation, and express his regret to this meeting that he is unable to be present.

"I now turn to the work of the Badische Anilin- & Soda-Fabrik on the technical development of the process. This work was of course at once taken up in 1908 after the first communications of Professor Haber, and Dr. Carl Bosch was entrusted with it. In conjunction with his colleagues and with equal energy and experience in the field of chemistry and engineering he has successfully carried out the practical application of the process."

Work of the Badische Company

The problems to be solved were quite new and strange and demanded the mastery of very unusual difficulties. Although working with compressed gases under pressure at very low temperatures was already known in the industry, the problem here was the totally different one of constructing apparatus which should be large enough and at the same time able to withstand the high pressure with temperatures not far from a red heat. How well founded were the doubts as to the possibility of a solution of this task can be gathered from the instance of the wrought iron autoclaves commonly used in the color industry. Here, in spite of a very low range of temperature of at most about 280 deg. C. only pressures of from 50 to 100 atmospheres at the utmost come into consideration. But above 400 deg. C. iron loses its solidity to a very extraordinary degree.

There is further the circumstance that the metals which come into consideration for the construction of the apparatus, and especially iron, are chemically attacked above certain temperatures by the gas mixture under pressure. Although the formation of iron nitrid from iron and ammonia, which could have been expected according to the work of Frémy and others, can be avoided, yet it is found, for example, that steel containing carbon loses its carbon at the temperatures in question owing to the action of the hydrogen, so that its capability of withstanding pressure is reduced to a minimum. It was further found, when using iron itself, that it is completely changed in its qualities, chiefly by taking up

Materials for Apparatus Construction

[1] See the sketches in Haber's article in the Zeit. f. Elektrochemie, 16 (1910) pp. 244-5, and also British Patent No. 17951 09.

hydrogen. Again, at such high temperatures iron is pervious to quite a remarkable degree to hydrogen under high pressures. "The question of materials for the apparatus therefore raised at once considerable difficulties, but at length these were more than overcome by suitable construction, details of which, I am sure, you will not expect from me to-day. The danger of serious explosions or of great sudden flames of hydrogen, if the apparatus happens to become defective, can be guarded against by setting it up in bomb-proof chambers."

Great care must naturally be taken that oxygen or air does not get into the apparatus or the piping, for at the high pressure obtaining the explosion range is reached with merely a slight percentage of oxygen. Special devices are used to watch over this content of oxygen, and immediately a definite percentage is touched the alarm is automatically raised. Besides this the proper constitution of the gas mixture in circulation is controlled by analysis from time to time.

The ammonia can be removed either by being drawn directly from the apparatus in liquid form, or an absorption agent can be suitably introduced into the apparatus. The simplest absorbent, water, has been found to be suited for this purpose; under the pressure used a concentrated solution of ammonia is secured. Any ammonia that may remain in the gas after the bulk has been removed by one or other of these methods can be further removed by special chemical means, if it is not preferred simply to leave it in the circulating gases.

As before mentioned, Haber observed that there are contact agents which are much more active than those proviously known (osmium and uranium being indeed found to be much more active than pure iron prepared from oxalate of iron or oxid of iron, platinum, pure manganese, chromium, and nickel, already at considerably lower temperatures). The Badische Anilin- & Soda-Fabrik therefore decided to study the various catalysts very minutely.

In the course of these investigations, the new fact discovered, that ammonia catalysts in general are made more active by the presence of certain foreign bodies, has proved to be of prime importance. Among these "promotors," as they have been termed, are oxids, hydroxids, or salts of the alkalies, of the alkaline earths and the earth metals, further many other substances of the most varied nature, especially other metal compounds or metals themselves. In many cases just a minute quantity suffices to raise the catalytic activity. This trait is common to all catalysts, for there is not one but its activity can be raised by these means. Care must, however, be taken (for reasons to be discussed later on), not to choose such mixtures that metalloids such as sulfur, selenium, tellurium, phosphorus, arsenic, boron, etc., under the conditions prevailing, are incorporated in the catalyst. Similarly compounds of metals with a low melting point which are readily reduced by hydrogen and which themselves do not act as catalysts must be avoided; such metals themselves as lead, tin, zinc and bismuth must also not be added.

Catalytic Agents

The promoters mentioned can be added either to the prepared catalyst or to the substances used in its preparation, or the catalyst can be prepared from such materials as already contains such additions in suitable mixture (for example magnetic ironstone). Under certain circumstances the action of these foreign bodies is specially powerful, viz. if the metals, or oxids, or carbonates, or other compounds which are converted into oxids on heating, are first heated to high temperatures, preferably to melting point, and so that the resulting product consists chiefly of oxids. When proceeding in this way with metals, for instance iron, of course sufficient oxygen or oxygen-producing compounds must have access. The mass of oxids obtained as described is suitably broken up and filled into the contact stove either directly or after reduction. In this case extremely small quantities of foreign substances suffice to secure a high and continuous activity of the contact mass.

We consider the marked activity of catalysts prepared in this way to be in the first place due to the fact that the additions mentioned dissolve, on heating, in the highly heated metallic oxid or become finely divided in it, and that in this way during the following reduction a sort of skeleton, which however is hardly to be detected, is formed inside the metallic mass. This effectually prevents a diminution of the surface and therefore also of the catalytic properties of the mass.

It was then further found that good results can also be achieved with pure iron, that is to say, that we can work with it at temperature of, for example, not much above 600 deg. C., thus if the iron intended for the catalysis is prepared from the oxid or other iron compound at a comparatively low temperature, preferably not above 600 deg. C. It can also be prepared by highly heating pure iron oxids, or pure iron in the presence of oxygen, preferably to melting point, and by reducing the mass of oxid preferably at a not too high temperature.

Also manganese, which is related to iron, gives under a specific condition good results, without the addition of foreign substances. This condition is that care be taken to free completely the mixture of nitrogen and hydrogen, before it enters the contact space, from oxygen, either free or combined, for instance as steam or water. Merely drying with calcium chlorid is not sufficient. In the case of several other catalysts too a similar careful drying has proved to be useful

Again, it has been found that another member of the iron group, molybdenum, is by itself an excellent catalyst. Compounds of molybdenum can also be used, for instance molybdic acid or ammonium molybdate.

Under certain conditions, not published as yet, tungsten, either the metal itself or as an alloy or a nitrogen compound, has been found to be a suitable catalyst. (Such conditions are e. g. that tungsten, or its compounds mentioned, is prepared at temperatures not much above 600 deg. C., that they are prepared from tungsten compounds by means of ammonia, in which case there is no restriction to a temperature of about 600 deg. C.)

Another discovery of first-class importance for the industrial application of the catalysis of ammonia was the recognition of the fact that there are special poisons, so to speak, for the reaction. That is to say, there are substances which hinder or prevent the reaction, although the contact mass does not suffer a noticeable chemical change, envelopment or destruction. In the literature there was no indication whether there were poisons at all for the contact mass in the catalytic manufacture of ammonia, or what their nature would be. In actual manufacture such contact poisons were known only in the case of the catalysis of sulphuric anhydrid and even here only when platinum was used. When employing other contact bodies, such as iron oxid, or burnt pyrites, there was nothing known of contact poisons; on the contrary, it has ever been shown that the presence of arsenic, which is a poison for platinum, has actually a favorable action when iron oxid is used as catalyst.

Poisons for the Reaction

It has now been ascertained that some of the poisons in the synthesis of ammonia are of quite a different nature from those of the sulphuric acid process, they are, for instance, sulphur, selenium, tellurium, phosphorus, arsenic, boron, or the compounds of these elements such or sulphuretted hydrogen, arsenic hydrid, phosphorus hydrid, as also many carbon compounds and certain metals of low melting point which can readily be reduced by hydrogen from their compounds, for example, lead, bismuth and tin, which do not act catalytically. Oxygen-sulphur compounds, such as SO_2, which acts directly and smoothly in the sulphuric acid catalysis, are very poisonous. Extremely minute quantities of these bodies, which are almost always present even in the purest commercial products or in the so-called pure gases, suffice to render the catalysts absolutely inactive or at least to diminish their action very seriously. Thus iron, for example, prepared from ordinary

iron oxide with a content of one per thousand of sodium sulphate, is, as a rule, inactive. Iron containing one-tenth per cent of sulphur is generally quite useless, and even with one hundredth per cent is of very little use, although in appearance and when examined with the ordinary physical and chemical methods no difference at all can be detected as compared with pure iron.

The recognition of these facts gave rise to two problems:

(a) The preparation of contact masses free from poison or the removal of such poisons from them, and

(b) Freeing the gases to be acted on catalytically from all contact poisons.

In order to free the contact bodies from these harmful substances the ordinary methods for removing them can, of course, be applied. The contact action can also be improved by heating contact metals which are inactive or of little use owing to the presence of contact poisons, in the presence of oxygen or of bodies yielding oxygen. Or the metals can be heated, for instance, in the presence of oxygen, with the addition of suitable compounds such as bases, and the resulting products reduced. These operations can be repeated if necessary.

Annihilation of Poisons

If more of such a body as mentioned is added than is necessary it may act not merely by removing the poisons, but promote the yield.

On the other hand, it is necessary to take the greatest care that nitrogen and hydrogen are free or freed completely from all contact poisons. Thus a trace of sulphur, one part per million, in the gas mixture can, under certain conditions, be injurious, so that even electrolytically prepared hydrogen must generally be further specially purified. The minute purification of the gases is even more important when hydrogen prepared, for example, from water gas is used. The impurities, too, taken up from iron piping play sometimes an important part, and impurities which get into the gases during the compression, such as machine oil, often have a harmful effect.

The best method of removing impurities from the gas mixture depends in turn on the nature of these impurities and consists, for instance, according to the case, in filtering, washing, conducting over solid absorption agents and so on. One good method is to bring the gases into contact with the material of which the contact mass is prepared at a raised temperature, before passing them over the actual catalyst. The material takes up the impurities, and must, of course, be renewed from time to time.

The negative results of earlier investigators in the formation of ammonia when using base contact metals, according to which nitrogen and hydrogen do not combine in the presence of iron, are probably due, for the most part, at least, to the use of metals or gases which were not free from contact poison.

The previous inquiries had not the remotest idea that sulphur in the contact metal could be injurious is evident from the fact that they passed the gases without hesitation through concentrated sulphuric acid in order to dry them. The sulphuric acid thus taken up and the sulphur dioxide often contained in it can poison even the best catalyst very speedily and render it unfit for use. Or the contact metals were sometimes prepared directly from the sulphates, although a metal sufficiently free from sulphur can scarcely be obtained by this method.

A painstaking study, for which we are indebted principally to Dr. A. Mittasch and which involved literally many thousands of experiments, has afforded an insight into the importance of substances of the most varied nature as promoters and poisons and thus a sure foundation has been prepared for a reliable continuous manufacture with a good yield of ammonia.

The production of ammonia was then demonstrated by Dr. Bernthsen.

The question has not yet been touched upon in the foregoing, how the elements nitrogen and hydrogen which are requisite for the new ammonia process can best be produced on a technical scale. Theoretically, the task would be unusually simple. If one remembers that the terrestrial atmosphere according to the studies of A. Wegener and others consists of practically pure hydrogen at a height of about 120 kilometers, indeed at a height of about 70 kilometers consists of almost exactly one volume of nitrogen and three volumes of hydrogen besides a trace (about one-half per cent.) of oxygen, "you will understand that all the conditions were given for an ammonia factory according to Jules Verne. For it would then merely be necessary to suck down the gases from the higher strata of the atmosphere by a sufficiently long pipe line.

Production of Nitrogen and Hydrogen

"For us, poor mortals, matters are not so ideally simple, for, as the poet says, 'hart im Raume stossen sich die Sachen.' Fortunately, however, there is no great difficulty in separating nitrogen from the air, either by physical means, according to Linde's process, or chemically, by removing the oxygen with glowing copper, burning hydrogen, or the like."

And for the preparation of hydrogen in recent times a great deal of useful work has been done, too, owing to the extensive growth of its field of application. In certain works it is at disposal in large quantities as a by-product of the electrolysis of common salt. Besides this it can be produced, for example, by passing steam over red-hot iron, or from water-gas, for instance, by separating its constituents hydrogen and carbon monoxide by cooling to a very low temperature. All the methods of preparation which come into consideration we have of course minutely examined; owing to the comparatively trifling differences in the cost of production various methods can be employed. At all events, both elements, nitrogen and hydrogen, are at the disposal of the new industry to any extent and sufficiently cheap.

As the production of these elements is not confined to the presence of cheap water power, all those countries where the manufacture of calcium nitrate, owing to the want of such power, is not practicable, as for instance in Germany, are now in a position to profit by the new industry. As I remarked at the outset, there is every reason to assume that this industry will find a fruitful field of employment in America, where the demand for nitrogen-manures will soon be greater than hitherto.

It can also be regarded as certain that the development of this new industry will not take place at the cost of other branches of industry and commerce. The present annual requirements for nitrogen-manures and their continued growth reached the remarkable total of 467.2 + 326, i. e., 793.2 million marks (about 190 million dollars) in 1911, and each year sees an increase. In the last few years the increased demand for ammonium sulphate amounted to about 10 per cent. The increase of production from 1910 to 1911 amounted to 69,000 tons, and from 1908 to 1911 on the average as much 110,000 tons, or 110 million kilograms valued at about 30.6 million marks (7.3 million dollars).

No Harm to Established Industries

Similarly the nitrogen requirement of the world for manure purposes in the form of saltpeter is growing. Chili exported in 1908 about 2,052,400 tons of saltpeter, and already in 1911 the figure was about 2,449,400 tons, that is an annual increase of nearly 150,000 tons valued at approximately 29 million marks (7 million dollars). Indeed the European deliveries, according to the latest reports, from January to the end of June, 1912, reached as much as 1,449,000 tons, a demand which Chili was hardly able to meet. The average annual increase from 1901 to 1911 amounted to 99,500 tons. That is to say, taking saltpeter and ammonium sulphate together and reckoning only the average increases, calculated on nitrogen, we have an annual increase in production of about 38,000 tons nitrogen.

corresponding to nearly 185,000 tons of ammonium sulphate.

It can thus be seen what enormous quantities of synthetic ammonium sulphate must be produced to affect the total production by as much as one year.

The thanks of the meeting were voted to Dr. Bernthsen for his brilliant lecture, the motion being made by Dr. Eyde and seconded by Dr. Duisberg.

The Photochemistry of the Future.

General Lecture by the Representative of Italy.

An exceedingly interesting and suggestive address, looking far ahead in the future and covering the subject from the broadest viewpoint, was presented by **Giacomo Ciamician**, of Bologna, Italy, on the afternoon of Wednesday, September 11, at the College of the City of New York.

Modern civilization is the daughter of coal, for this offers to mankind the solar energy in its most concentrated form; that is in a form in which it has been accumulated in a long series of centuries. The earth still holds enormous quantities of it, but coal is not inexhaustible. The problem of the future begins to interest us. Is *fossil* solar energy the only one that may be used in modern life and civilization? That is the question.

How to Use the Energy from the Sun

Assuming that the solar constant is three small calories a minute per square centimeter, that is thirty large calories a minute per square meter or about 1800 large calories an hour. We may compare this quantity of heat with that produced by the complete combustion of a kilogram of coal, which is 8000 calories. Assuming for the tropics a day of only six hours sunshine we should have, for the day, an amount of heat equivalent to that furnished by 1.35 kg of coal, or 1 kg in round numbers.

For a square kilometer we should have a quantity of heat equivalent to that produced by the complete combustion of 1000 tons of coal. A surface of only 10,000 square kilometers receives in a year, calculating a day of only six hours, a quantity of heat that corresponds to that produced by the burning of 3,650,000,000 tons of coal, in round numbers 3,000,000,000 tons. The quantity of coal produced annually (1909) in the mines of Europe and America is calculated at about 925,000,000 tons and, adding to this 175,000,000 tons of lignite, we reach 1,100,000,000 tons, or a little over one billion.

The Amount of Energy Received from the Sun

Even making allowances for the absorption of heat on the part of the atmosphere and for other circumstances, we see that the solar energy that reaches a small tropical county—say of the size of Latium—is equal annually to the energy produced by the entire amount of coal mined in the world! The desert of Sahara with its 6,000,000 square kilometers receives daily solar energy equivalent to 6,000,000,000 tons of coal! This enormous quantity of energy that the earth receives from the sun, in comparison with which the part which has been stored up by the plants in the geological periods is almost negligible, is largely wasted. It is utilized in waterfalls (white coal) and by plants.

The energy produced by water power during the period of one year is equal to that produced by 70,000,000,000 tons of coal. This is very small, as might be expected, in comparison with the total energy that the sun sends to the earth every year. Let us now see what quantity of solar energy is stored by the plants; on the total surface of the various continents, which is 128,000,000 square kilometers, there is a yearly production of 32,000,000,000 tons of vegetable matter, which, if burnt, would give the quantity of heat that corresponds to the total combustion of 18,000,000,0000 tons of coal. It is not much, but even this is seventeen times as much as the total present production of coal and of lignite.

In the first part of his lecture the author discusses this question:

A Question on Possibilities

"Now let us consider the first part of our subject. Is it possible or, rather, is it conceivable that this production of organic matter may be increased in general and intensified in special places, and that the cultivation of plants may be so regulated as to make them produce abundantly such substances as can become sources of energy or be otherwise useful to civilization? I believe that this is possible. It is not proposed to replace coal by organic substances produced by plants; but it is conceivable that this organic matter may be utilized more satisfactorily than is now the case."

By increasing the concentration of carbon dioxide up to an optimum value (1 to 10 per cent according to Kreuseler) and by using catalyzers, it seems quite possible that the production of organic matter may be largely increased, making use, of course, of suitable mineral fertilizers and selecting localities adapted to the purpose, owing to the climate or the condition of the soil. The harvest, dried by the sun, ought to be converted, in the most economical way, entirely into gaseous fuel, taking care during this operation to fix the ammonia (by the Mond process for instance) which should be returned to the soil as nitrogenous fertilizer together with all the mineral substances contained in the ashes.

We should thus get a complete cycle for the inorganic fertilizing substances, the only waste being that common to all industrial processes. The gas so obtained should be burnt entirely on the spot in gas engines and the mechanical energy thus generated should be transmitted elsewhere or utilized in any way that seems advisable. We need not go into details. The carbon dioxide, resulting from the combustion, should not be wasted but should be returned to the fields. Thus the solar energy, obtained by rational methods of cultivation, might furnish low-priced mechanical energy.

Plants in Competition with Coal

But the problem of the utilization of plants in competition with coal has another and more interesting side. First of all we must remember the industries which have their basis in agriculture: the cotton and other textile industries, the starch industry, the production of alcohol and of all fats, the distillation of wood, the extraction of sugar, the production of tanning substances and other minor industries. All these industries are susceptible of improvement not only by the introduction of more advantageous technical devices in the treatment of the raw materials but also by a largely increased production of the raw materials. Let us think for an example of the progress made in the production of beet sugar.

The plants are unsurpassed masters of—or marvellous workshops for—photochemical synthesis of the fundamental substances, building up from carbon dioxide with the help of solar energy. They also produce the so-called secondary substances with the greatest ease. These latter are usually found in the plants in small quantity and are of value for special reasons. The alkaloids, glucosides, essences, camphor, rubber, coloring substances and others are of even greater interest to the public than the fundamental substances on account of their high commercial value. In this field a battle is raging between chemical industry and nature, a battle which does honor to human genius.

Up to now the products prepared from coal tar have almost always been triumphant. "I do not need to remind you of the various victories; but it is possible that these may prove to have been Pyrrhic victories. A great authority on organic industries considered recently what would happen in case, for any reason, there were a rapid increase in the price of coal tar and consequently of the substances contained in it. He pointed out the inevitable effect of this on the coal tar industries. We all remember with admiration the story of the great diffi-

culties that had to be met in the choice of the raw material for the production of indigo. It was necessary finally to use naphthalene because toluene could not be obtained in sufficient quantity.

"But it is not merely through a rise in the price of the raw materials that an industry may suffer; it may be brought to a standstill by a diminished interest and activity in a certain field of scientific study.

Industry and Science

It has been thoroughly established that modern industry is affiliated very intimately with pure science; the progress of one determines necessarily that of the other. Now the chemistry of benzine and its derivatives does not constitute the favorite field of research as it did during the second half of the last century. The center of interest is now to be found in the matters and problems connected with biology. Modern interest is concentrated on the study of the organic chemistry of organisms. This new direction in the field of pure science is bound to have its effect on the technical world and to mark out new paths for the industries to follow in the future.

"It is a fact that lately several organic industries have been successfully developed, outside of the field of benzine and coal tar. There are flourishing industries in essences and perfumes and in some alkaloids, like coca. In these industries products, which plants produce in relatively large amounts, are converted into products of higher commercial value. For instance everybody knows that essence of violet is now made from citral contained in lemon oil. This is a line along which we ought to follow because we are certain of making progress. It is to be hoped that in the future we may obtain rubber commercially in some such way.

"The question has still another side, which I believe deserves your attention; it concerns certain experiments recently made by myself together with Professor Ravenna at Bologna. It is not because we have arrived at any practical results that I refer to these experiments; but because they show definitely that we can modify to a certain extent the chemical processes that take place during the life of the plants. In a series of experiments made in an effort to determine the physiological function of the glucosides, we have succeeded in obtaining them from plants that usually do not produce them. We have been able, through suitable inoculations, to force maize to synthesize salicine. More recently, while studying the function of the alkaloids in the plants, we have succeeded in modifying the production of nicotine in the tobacco plant, so as to obtain a large increase or a decrease in the quantity of this alkaloid.

"This is only a beginning, but does it not seem to you that, with well-adapted systems of cultivation and timely intervention, we may succeed in causing plants to produce, in quantities much larger than the normal ones, the substances which are useful to our modern life and which we now obtain with great difficulty and low yield from coal tar? There is no danger at all of using for industrial purposes land which should be devoted to raising foodstuffs. An approximate calculation shows that on the earth there is plenty of land for both purposes, especially when the various cultivations are properly intensified and rationally adapted to the conditions of the soil and the climate. This development is the real problem of the future."

In the second part of his lecture the speaker pointed out that it may be asked whether there are not other methods of production which may rival the photochemical processes of the plants. "The answer will be given by the future development of photochemistry as applied to the industries and on this I have a few ideas to express.

Photography a Small Part of Photochemistry

The photochemical processes have not had so far any extensive practical application outside of the field of photography. From its very beginning photography has aroused a great deal of interest; it was taken up technically and, as usually happens in similar cases, it had a rapid and brilliant success. But notwithstanding the many applications photography represents only a small part of photochemistry. So far, photochemistry has only been developed to a very slight extent, perhaps because chemists have been attracted by problems which seemed more urgent. So it happens that, while thermochemistry and electrochemistry have already reached a high degree of development, photochemistry is still in its infancy.

"Now, however, we notice a certain awakening due to a series of studies concerning general problems and special processes, especially in the organic field, in which my friend Dr. Paul Silber and myself have taken an active part. Two recent publications, one by Plotnikow and the other by Benrath, bear witness to this. But much remains to be done both in theoretical and general photochemistry as well as in the special branches.

"The photochemical reactions follow the fundamental laws of affinity, but have a special character. They are especially notable for the small temperature coefficient and are, however, comparable—a fact which is not without technical importance—to the reactions which take place at very high temperatures. According to a brilliant idea of Plotnikow, luminous radiations produce a different ionization from that due to electrolytic dissociation; the separation of an ion requires a quantity of light which is determined by the theory of Planck and Einstein. The question is therefore related to the most recent and profound speculations of mathematical physics.

"For our purposes the fundamental problem from the technical point of view is how to fix the solar energy through suitable photochemical reactions. To do this it would be sufficient to be able to imitate the assimilating process of plants. As is well known, plants transform the carbon dioxide of the atmosphere into starch, setting free oxygen. They reverse the ordinary process of combustion. It has always seemed probable that formaledhyde was the first product of the assimilation; and Curtius has at last demonstrated its presence in the leaves of the beech trees. The artificial reproduction of a similar process by means of ultraviolet rays has already been obtained by D. Berthelot. With convenient modifications could not this now actually be done on the tropical highlands?

Fixing Solar Energy by Photochemical Reactions

"Yet the true solution consists in utilizing the radiations that pass through the entire atmosphere and reach the surface of the earth in large amounts. That a way of accomplishing this exists is proved by the plants themselves. By using suitable catalyzers it should be possible to transform the mixture of water and carbon dioxide into oxygen and methane, or to cause other endo-energetic processes. The desert regions of the tropics, where the conditions of the soil and of the climate make it impossible to grow any ordinary crops, would be made to utilize the solar energy which they receive in so large a measure all the year, that the energy derived from them would be equal to that of billions of tons of coal.

"Besides this process, which would give new value to the waste products of combustion, several others are known, which are caused by ultraviolet radiations and which might eventually take place under the influence of ordinary radiations, provided suitable sensitizers were discovered. The synthesis of ozone, of sulphur trioxide, of ammonia, of the oxides of nitrogen, as well as many other syntheses, might become the object of industrial photochemical processes.

"It is conceivable that we might make photochemical batteries or batteries based on photochemical processes, as, for instance, in the experiments of C. Winther.

"Passing to the field of organic chemistry, the reactions caused by light are so many that it should not be difficult to find some which are of practical value. The action of light is especially favorable to processes of reciprocal oxidation and reduction which give rise to or are associated with phenomena of condensation. Since the common condensation is that of the

aldolic type there is much hope for the future, the aldolic condensation being the fundamental reaction of organic synthesis.

"To get an idea of the variety of photochemical reactions we may confine ourselves to a systematic study of the ketones and alcohols. In ordinary organic chemistry the reactions often take place in some definite way; but the photochemical reactions often furnish surprises and proceed along quite different lines. From the very first experiments we knew that benzophenone did not form addition products with ethyl alcohol, but was converted into pinacone at the expense of the alcohol, which was oxidized to aldehyde. Proceeding with the study of aliphatic ketones, similar to acetone, we have this year discovered a remarkable fact. Methylethylketone condenses with itself and forms the paradiketone, reducing itself at the same time to secondary butyl alcohol.

Ketones and Alcohols

"Of course the synthesis of diketones by light could not be an isolated reaction; we had previously noticed the formation of diacetyl; acetonylacetone is found, as we now know, among the products of acetone in solution in ethyl alcohol and it is also possible that the metadiketones, such as acetylacetone, for instance, may be prepared photochemically. These reactions have a special importance on account of the special character of the diketones and their tendency to change in all sorts of ways. From them derivatives of benzene can be obtained as well as of pyrrazol and isoxazol, of quinoline, of furfurol, of thiophene and of pyrrol.

"In regard to this last change I wish to remind you that tetramethylpyrrol corresponds to the paradiketone previously referred to. If I dare to be reckless, as you may see I am at this moment, contrary to my custom, but perhaps urged thereto unconsciously by the American genius which heeds no obstacles, I may refer to the relations between the polysubstituted pyrrols with alcohol radicals and chlorophyll, and I may see in these reactions the possibility of the synthesis of this fundamental substance by means of an artificial photochemical process. Its formation in plants, like its function, is due to a photochemical process; we do not know, however, whether and in what measure light enters into all the synthetic plant reactions, from which originate the various substances which we find in plants. The research should proceed together in the two fields; phytochemistry and photochemistry will be of great help one to another. Industrially this co-operation might have a great future: the raw materials obtained from the plants might be refined through artificial photochemical processes.

"Lately we have been interested intensely by the changes that some substances of the group of the terpenes and of the camphors undergo when exposed to light, especially through hydrolytic processes. So far, indeed, our experiments have taught us that light can spoil rather than improve essences. The cycloketones, for instance, are hydrolized and give the corresponding fatty acids; the cycloesanone gives capronic acid and menthone gives decylic acid.

Terpenes and Camphors

"In photochemistry, however, one reaction does not exclude the other; the reactions may be reversed as some recent experiments with ultraviolet rays demonstrate; for the ultraviolet rays sometimes reverse reactions caused by less refrangible radiations. It is important to find suitable sensitizers and catalyzers. We can see what the future has in store for us from such reactions as the photolysis of the ketones, which often accompanies the hydrolysis, and by means of which we prepare isocitronellal, for instance from menthone, or the transformation of camphor into an unsaturated cycloketone, etc. The analogous breaking down of pinacoline into butylene and acetic aldehyde is remarkable because it demonstrates what violent decompositions light may cause. It may be an enemy, but just on account of that it is necessary to be familiar with the weapons of the adversaries in order to be able to conquer them and to avail ourselves of their strength.

"I do not believe, however, that the industries should wait any longer before talking advantage of the chemical effects produced by light. The polymerizations, the isomeric changes, the reductions and oxidations with organic and inorganic substances, and the autoxidations which light causes so easily should already find profitable applications in some industries if researches were carried out carefully with this in mind. The action of light on nitric and nitrosilicic compounds, as we know it from experience, is one that ought to be utilized profitably. Our own transformation of orthonitrobenzoic aldehyde into nitrosobenzoic acid has recently been studied by various chemists, and has been made use of by Pfeiffer, who prepared a nitrophenylisatogen from chlorodinitrostilbene.

"This reminds us of the not less known transformation of benzylidene orthonitroacetophenone into indigo by Engler and Dorant and makes us foresee a new field in the photochemical production of artificial colors and dye-stuffs. The scope of studies on this subject ought not to be limited to preserving colors from fading, bleaching and all changes produced by light. The photochemistry of colors and dye-stuffs ought to furnish new methods of preparation and of dyeing. Very encouraging experiments have already been made with diazoic compounds and mention should be made of the recent observation of Baudisch that alpha-nitrosonaphthylhydroxylamine is changed on the fibre to azoxynaphthalene when exposed to light. The autoxidation of leuco compounds by light is an old practice of which the ancients availed themselves for preparing purple; now the process is explained, thanks to the familiar researches of Friedländer, but it is clear that a great deal remains to be learned in this field.

Photochemistry of Colors and Dyestuffs

"Phototropic substances, which often assume very intense colors in the light, and afterwards return in the darkness to their primitive color, might be used very effectively. Such substances might well attract the attention of fashion rather than fluorescent materials which give the impression of changing colors. The dress of a lady, so prepared, would change its color according to the intensity of light. Passing from darkness to light the colors would brighten up, thus conforming automatically to the environment: the last word of fashion for the future."

"Solar energy is not evenly distributed over the surface of the earth; there are privileged regions, and others that are less favored by the climate. The former ones would be the prosperous ones if we should become able to utilize the energy of the sun in the way which I have described. The tropical countries would thus be conquered by civilization which would in this manner return to its birthplace. Even now the strongest nations rival each other in the conquest of the lands of the sun, as though unconsciously foreseeing the future.

Peroration

"Where vegetation is rich, photochemistry may be left to the plants and by rational cultivation, as I have already explained, solar radiation may be used for industrial purposes. In the desert regions, unadapted to any kind of cultivation, photochemistry will artificially put their solar energy to practical uses.

"On the arid lands there will spring up industrial colonies without smoke and without smokestacks; forests of glass tubes will extend over the plains and glass buildings will arise everywhere; inside of these will take place the photochemical processes that hitherto have been the guarded secret of the plants, but that will have been mastered by human industry which will know how to make them bear even more abundant fruit than nature, for nature is not in a hurry and mankind is. And if in a distant future the supply of coal becomes completely exhausted, civilization will not be checked by that, for life and civilization will continue as long as the sun shines! If our black and nervous civilization, based on coal, shall be followed

by a quieter civilization based on the utilization of solar energy, that will not be harmful to progress and to human happiness.

"The photochemistry of the future should not however be postponed to such distant times; I believe that industry will do well in using from this very day all the energies that nature puts at its disposal. So far, human civilization has made use almost exclusively of fossil solar energy. Would it not be advantageous to make better use of radiant energy?"

* * *

Dt. *Wilder D. Bancroft* offered a vote of thanks, which was seconded by Dr. *L. H. Backeland*. Both emphasized the prominence of Italians among the men of achievement in art, literature, science, and music in the past, and declared that it was peculiarly befitting that Dr. Giacomo Ciamician, of Italy, should present a lecture with such a grasp of the possibilities of chemistry of the future, which would render man's triumph in science and accomplishment for good still greater.

Dr. Nichols, President of the Congress, presided.

Joint Meeting of Sections on Metallurgy and Mining, Fuels and Asphalt.

The first paper presented by this section on Wednesday was the following.

Beehive Coke Ovens.—A paper on the beehive coke oven industry of the United States, by **A. W. Belden** of the Bureau of Mines Experiment Station, Pittsburgh, Pa., reviews the industry under the following headings: Beehive ovens, longitudinal ovens, beehive oven with arrangement for utilizing the waste heat of gases, beehive coking in the several coal fields of the United States.

The Spontaneous Combustion of Coal, a paper by **Horace C. Porter** and **F. K. Ovitz**, of the Bureau of Mines, Pittsburgh, Pa.

Fires are frequently caused in coal piles, coal bins and coal bunkers of ships by the accumulation of heat from so-called spontaneous chemical reactions. Spontaneous heating is responsible for large losses in stored fuel. Even though actual fire does not occur, the deterioration by oxidation rapidly increases as the coal becomes heated. The storage of large quantities of coal, 500,000 tons and more, at one point for a period of one year and longer, is becoming a common practice, by reason of the uncertainties of supply due to strikes and transportation difficulties; therefore the reduction of losses to a minimum in such valuable quantities of stored material is an economic problem of importance.

The increase of temperature in stored coal depends upon certain physical conditions. First, temperature is the large factor and storing of coal in warm places greatly increases the liability to spontaneous combustion. Second, dust or fine coal must be considered as a large factor. Third, the rate of oxidation of coal is a function of the partial pressure of oxygen present, and, therefore, on the rate of flow of air. The fourth factor to be mentioned is the degree of freshness of the coal surface. Freshly mined coal absorbs oxygen more rapidly than coal which has been exposed for some time.

Following this paper, **Miss D. Hill** read a paper on **The Natural Gas Industry,** which was followed by **R. Lessing** on **A New Coking Test for Fuels.**

In addition to these papers, which were read by their authors, the following interesting paper was announced by title **Fuel Economy of the Cupola,** by **J. J. Porter.** We shall present an abstract of this paper in a later issue.

In the section on **Agricultural Chemistry** the paper by *B. L. Hartwell* and *P. H. Wends* on the effect of sodium manures on the percentage of sugar in certain plants, by *B. E. Curry* and *T. O. Smith* on soil potassium, and by *H. A. Huston* on field test with fertilizers, were presented.

Section on Analytical Chemistry

The following papers were read:

A Method for the Systematic Qualitative Detection of Barium and Strontium. By **L. J. Curtman** and **E. M. Frankel** of the College of City of New York, N. Y.

The previous work of the authors has shown that the systematic qualitative detection of barium is distinctly unreliable. They have devised a scheme of analysis by which small amounts of the alkaline earth metals may be detected. The method consists in the precipitation of the alkaline earth metals, together with part of the lead as sulphates with dilute sulphuric acid and alcohol, from a solution of definite acidity. After extracting the lead sulphate with ammonium acetate, the alkaline earth sulphates are converted to carbonates by boiling with sodium carbonate solution. The carbonates are then dissolved in acetic acid and the resulting solution analyzed in the usual manner. Numerous test analyses prove the method to be trustworthy.

The Determination of the Sensitiveness of the Hydroxide Reactions for the Common Metals. By **L. J. Curtman** and **A. D. St. John,** of New York.

The hydroxide reactions of the metals are perhaps the most common as well as the most important of those which take place in the wet way; yet no systematic work has been done to determine the delicacy of these reactions. The present work was therefore undertaken to supply this information, the need for which was felt in qualitative work. From the fact that the hydroxides studied were formed by precipitation, it might appear that the desired results could be calculated from the figures for the respective solubility products of the hydroxides; but it unfortunately happens that, with few exceptions, these figures have not as yet been determined; moreover, this information, even if available, would give but a rough idea of the sensitivity limit, for the reason that the final result of a sensitivity determination is largely an optical phenomenon that is controlled by factors some of which are not included in the law of mass action. Chief among these factors are those which affect the visibility of the precipitate in very dilute solutions; such as its form, density, and color. In order to obtain comparable results, all the experiments were carried out under uniform conditions. The general procedure was as follows: In separate experiments diminishing amounts of metal, in the form of a solution of one of its salts, were treated in test tubes with a slight excess of a 10 per cent solution of either ammonia or sodium hydroxide, depending upon the solubility of the precipitate in an excess of either, and the tubes examined for a precepitate. The final volume in each case, including the reagent added, was 5 cc. Lead, silver, mercury, bismuth, copper, cadmium, iron, aluminium, chromium, nickel, Cobalt, zinc, manganese and magnesium were investigated.

A Study of the Sensitiveness of the Bead and Lead Dioxide Tests for Manganese with Special Reference to the Interference of Iron. By **L. J. Curtman** and **A. D. St. John,** of New York.

From the results it appears that the lead dioxide test for manganese is unreliable in the presence of three or four hundred parts of iron, unless a fairly large amount of manganese is present such as 0.2 mg. when a somewhat larger ratio of iron does not interfere with the test. On the other hand, the bead test is efficient with larger amounts of iron provided enough manganese (0.005 mg.) is introduced into the bead

The Influence of Non-Volatile Organic Matter and Certain Acids on the Precipitation of the Ammonium Sulphide Group of Metals. By **L. J. Curtman** and **H. Dubin,** of the College of City of New York, N. Y.

The effect of a number of non-volatile organic substances to prevent or hinder the precipitation of Al, Cr and Fe by NH_4OH was investigated. The following was found to be the order of interference: Citric acid, tararic acid, dextrin, sucrose, glucose, and lactose. The first offered the greatest

interference while sucrose, glucose and lactose interfered very slightly in the precipitation of the trivalent metals of Group III. Tables are given showing the effect of each of the above substances under conditions which prevail in qualitative work. A study was also made of the influence of certain acids in causing the precipitation of the alkalne earth metals and Mg in the third group. It was found that two grams NH_4Cl which are formed in the course of the analysis, are sufficient to prevent any interference by boric acid or borates; with fluorides, however, this was not found to be the case, even when the quantity of NH_4Cl was increased. The effect of varying quantities of oxalates and phosphates respectively on the precipitation of Ba, Sr, Ca and Mg in the third group was also investigated.

Symposium on Corrosion.

At the joint session of the Sections on Electrochemistry and on Paints held on Wednesday afternoon the following six papers, all dealing with the corrosion question, were presented:

The Influence of Cinders of the Corrosion of Iron Imbedded in Clay.

A paper by **Walter B. Schulte** points out that investigations of corrosion of underground structures occasionally reveal cases of corrosion under certain conditions which preclude a consideration of stray currents from electric railways as the cause. Filled ground, especially that containing cinder, coal and furnace products, is found harmful, the reasons of which are ascribed to the formation of sulphuric acid from the sulphur in the material and to the electrolytic corrosion set up by the iron in contact with the carbonaceous material which is at a lower potential than the iron.

The objection to the former theory is that after a severe heating the sulphur is usually expelled. Cases of corrosion also have been noticed where the carbon bed lay near the surface of the ground and was not in contact with the iron at the locality where corrosion was taking place. If the carbon bed is connected to the iron at some other place an active couple will be formed which will produce current to cause corrosion of the iron. Polarization will tend to decrease this current, but this polarization is minimized if air has access to the carbon bed.

Measurements of current flow and potentials were made in the laboratory with apparatus which approximated the conditions found in the field. A weighed iron plate was imbedded in clay on the top of which rested a bed of carbon, electrical connection between the two being made by a wire circuit containing a switch. Readings of current and voltage were made at different intervals during the run of 58 days. Single potentials of the carbon and iron against the clay were also measured.

Initial single potentials—carbon	0.638 volts
Initial single potentials—iron	0.204 volts
Total	0.842 volts
Initial current	.052 amp.

Average voltage 0.35 volts; average current .03 amp.

The corrosion efficiency of the plate was found to be 150 per cent.

The average current flowing would destroy about ¼ lb. of iron per year.

A gas main lying near a water main, each buried in a different soil, was found corroded. The corrosion was explained by the fact that the mains were at different potentials to the soils in which they were buried, and that the connection on the consumer's premises afforded a path for the current so that a large active electrolytic couple was formed.

Corrosion of Metals in Contact.—In a paper on **A Method for Testing the Mutual Corrosive Effect of Metals,** by **Hugo H. Hanson** and **Warren K. Lewis** of the Massachusetts Institute of Technology, Boston, Mass., the authors describe a method for determining the influence of one metal on the corrosion of another with which it is in contact. The method is based in principle on the electrolytic theory of corrosion.

The method consists in connecting electrodes of the two metals through an ammeter, keeping the solution about the electro-negative metal saturated with air and measuring the current in the external circuit. The distance of the electrodes, the concentration of the electrolyte, the resistance of the external circuit and the temperature must be kept constant.

To illustrate the utility of the method, tests were made of the action of alloys of zinc and copper on the corrosion of iron. The action of alloys of tin and lead on iron was also investigated. Terne-plate is claimed to resist corrosion better than tin. But the authors calculate from their results that lead accelerates the corrosion of iron far more than tin, and that lead-tin alloys accelerate increasingly with the proportion of lead. If terne-plate is really the more resistant, it must be on account either of the smaller number of pin-holes, due to a better adhesion of the coating, or of a different structure of the holes themselves, which interferes with corrosion.

Electrolytic Method for the Prevention of the Corrosion of Iron and Steel.

This paper was presented by **J. K. Clement** and **L. V. Walker,** of the Bureau of Mines, Washington, D. C. The object of the investigation was to determine the current density required to prevent the corrosion of steel immersed in acid waters. The influence of the following factors was investigated.

a. Rate of stirring of electrolyte.
b. Amount of oxygen present in electrolyte.
c. Acid concentration.

The last named is probably of least importance, especially in dilute solutions. The rate of stirring of the electrolyte is the most important factor. With a low rate of stirring in $\frac{N}{150}$ H_2SO_4 a current density of 0.5 to 0.8 milliamperes per square inch reduces the corrosion loss to a negligible value. The change in the potential of the iron cathode corresponding to this current density was about 0.04 volt. It was found that the current density required to prevent corrosion can be calculated from the loss in weight of the metal under the given conditions, when not protected, and the electrochemical equivalent of the iron.

The authors reached the following conclusions:

It has been shown that the corrosion of iron submerged in sulphuric acid solutions may be prevented by imposing a counter emf. The density of the current required to prevent corrosion depends on various factors: acid concentration, amount of dissolved oxygen and degree of circulation of electrolyte. The influence of these factors has been studied and curves have been given showing the current density necessary under various conditions. It has been found that the current density required can be calculated, within the limit of experimental error, from the loss in weight of the metal under the given conditions when not protected.

Mill Scale as a Cause of Corrosion.—A paper on mill scale as a cause of the pitting of steel pipes, by **George C. Whipple** and **Melville C. Whipple,** New York City, N. Y., reaches the following general conclusions relative to short time tests for corrosion, and to the part played in corrosion by mill scale:

Accelerated corrosion tests of iron and steel plates made by immersion in strong acid solutions are of little value as indicating the probable corrosion of the metals in water under conditions of actual service.

Accelerated tests made in running water by the use of a current of electricity give results that indicate the *manner* in which the plates will probably corrode in service; that is, whether by pitting or by general corrosion.

When steel pipe lines fail, they do so by the formation of numerous pits that ultimately form holes and cause leaks. An

important factor in the formation of pits, commonly recognized but by no means fully appreciated, is the mill scale.

Steel plates that pit badly under the electrolysis test when the scale is left on do not pit after the scale has been removed.

A galvanic survey of the mill scale, made by determining the current that will pass through a sensitive galvanometer placed in the circuit of wires that connect the mill scale with the metal beneath, gives results that differ materially for wrought iron and steel, and from which an index of the uniformity of corrosion may be calculated that bears a general relation to the liability of the metals to form pits.

The electrolysis tests and the galvanic survey show that wrought iron has a less tendency to pit than steel, and that American ingot iron is intermediate between the two, but resembles steel more nearly than it does wrought iron.

Steels containing copper differ but slightly among themselves and from steel that contains no copper, in their tendency to form pits.

To protect steel or ingot iron against failure by pitting, the best remedy is the removal of the mill scale. Efforts should be made to reduce the expense of doing this, or to modify the character of the scale during its manufacture. This appears to be the direction in which future improvements in the manufacture of steel plates for pipe-lines should lie.

The paper was discussed at some length by Dr. Cushman, Mr. Gaines, Mr. Dewey and other speakers. The various speakers all emphasized that no sweeping conclusions could possibly be drawn from any one given set of investigations. While they all considered that the paper was quite interesting, it was thought that the samples did not warrant the conclusions which were drawn, especially as to the difference between wrought iron and steel. Dr. Cushman said that there were irons and irons and steels and steels, but that in either case if the manufacturer tries to get homogeneity and gets away from segregation effects he will improve his metal.

Influence of Various Elements on the Corrodibility of Iron.

A paper by **Charles F. Burgess** and **James Aston,** of the University of Wisconsin gives an account of tests on the corrodibility of seventy-two alloys made as part of an extensive investigation on electrolytic iron and alloys produced therefrom, carried out under a grant made a number of years ago by the Carnegie Institute. The test samples were first exposed to weather conditions for 162 days and after the removal of rust and weighing they were again subjected to a 20 per cent sulphuric acid solution for one-hour periods.

The results indicate that there is no direct relationship between the durability of iron alloys under acid and under atmospheric corrosion. Nearly all of the alloys were found to be more resistant to corrosion than the electrolytic iron itself. Copper was found to have decided protective action under acid corrosion and also some protective action under atmospheric corrosion. Nickel alloys where found to be most resistant to atmospheric corrosion, while silicon up to nearly 3 per cent was found to be decidedly detrimental from the corrosion standpoint.

The other alloys tested and reported upon are those of aluminium, arsenic, cobalt, lead, manganese, selenium, sulphur, tin and tungsten.

Rates of Rusting of Iron and Steel.

A paper by **James Aston** and **Charles F. Burgess,** of the University of Wisconsin, covers the results of a series of corrosion tests carried out at the Chemical Engineering Department of the University of Wisconsin during the winter, spring and summer of 1910 and 1911. The samples selected represented six different grades of commercial product of varying degrees of purity. However, while there is opportunity for comparison of the durability of the different materials, the endeavor was mainly to get at the effects of variations of testing conditions upon the rusting of iron and steel.

The material consisted of high purity open hearth iron, Swedish wrought iron, open-hearth steels, Bessemer rail steel and gray cast iron. In general the samples were finished to a uniform smooth surface and ½ in. x 1 in. x 2 in. in dimensions. Some sheet iron pieces were exposed, mainly of 16-gauge stock, and 3 in. x 3 in. in size, some with scale, others with scale removed.

Three samples of each of the above kinds of material were exposed to atmospheric conditions alone, and a duplicate set was subjected to the combined action of the weather and to discharge gases from a large chemical laboratory. The latter condition is one of partial acceleration analogous to the requirements for certain special uses.

One sample of each material was taken in after 75 days of exposure to normal winter conditions. After removal of the dust and determination of its amount these samples were exposed to a second rusting for a wet spring weather period of 75 days; the surface of these specimens was left in the condition resulting from the first rusting. A second sample of each material was removed after 150 days of exposure to winter and spring weather, together with the specimens above mentioned, which had been out for the second period of 75 days. The amount of rust was determined, all surfaces were reground and sulphuric acid corrosion tests made. Finally, after regrinding and weighing, most of the samples were again exposed to 139 days of dry summer weather. The sheet material was too much corroded by the acid attack to be available for this test. At the conclusion of the tests certain of the samples, some of which had been exposed for 139 days and others for 300 days, were examined for the amount of pitting which had occurred.

Tentative deductions can be drawn from the tests as to

(1) The relative corrodibility of the different kinds of iron and steel by "atmospheric," by "fume" and by "acid" attack.

(2) The reliability of accelerated tests by comparison of the data for the above conditions.

(3) The effect of various seasons of the year.

(4) The effect of accumulated rust in promoting or retarding further rusting.

(5) The influence of character of test piece; that is, whether in the form of bars or sheets.

(6) The retarding or accelerating influence of the scale on sheet samples.

(7) The consistency of duplicate tests on the same material.

(8) The effect of pitting.

All data were determined as grams per square inch per day, or grams per square decimeter per day, for the atmospheric tests, and per hour for the acid tests. However, all determinations are tabulated by means of a corrosion factor in order that the work might be one unit of a successive series of tests. The constant by which the corrosion factor is calculated is noted in the tables. Tables are given showing the corrosion factors for the various materials for the different periods and conditions of test. The influence of scale, accumulated rust and of pitting are also noted by means of tables.

The deductions in regard to the relative durability of the various kinds of iron and steel should not be too rigid; since single lots of each were used and the values should be checked by repeated tests. Also, the history of manufacture of all of the samples is not definitely known and in some cases is not entirely representative of present practice. For the other tests the evidences are more conclusive, since consistency in the results for the several series is fairly indicative of the effect of the condition of test.

There is no doubt that impurities in the material are of importance in determining its resistance to corrosion, but while some are of detriment others appear beneficial. Again, while heterogeneity of structure is a factor it appears to be overshadowed by other influences. This is brought out to a degree by comparison of typical microstructures of the several materials, and their durability. That absolute homogeneity of

steel but gives the minimum of corrosion is not borne out by the tests. The range of durability of the various materials on 300 days exposure to atmospheric conditions is about 1 to 5; with an average rate of corrosion of 5.78 grams per square decimeter per year. This, for a 16-gauge sheet, would mean complete rusting away in 11 years. This would be greater than the usual life, and it has not been demonstrated whether there is an accelerated or retardant action after the first year's period as used in the present tests.

For the sulphuric acid test the range of durability is from 1 to 116, and there is little direct relationship in the comparative acid and atmospheric tests, and even less when the acid test is compared to the special conditions obtaining in the fume corrosion. Evidently there are factors entering into the acid test which do not obtain under atmospheric conditions, and is not a satisfactory guide in determining the durability of materials.

It is shown that atmospheric corrosion is dependent upon the seasons of the year and upon the gaseous impurities present in the air and that such impurities affect different grades of iron and steel to different degrees. No one product is best suited to all conditions, and in dealing with a problem where corrosion is a factor a study of the service conditions is as important as a study of the materials themselves.

The accelerating influence of initial rust formation on subsequent rusting is demonstrated by the investigation. The results are very consistent for the atmospheric tests, but not so consistent for the fume conditions. Again, the black scale on sheet iron is shown to have little, if any, retarding effect; in fact, for these tests it was accelerating for the atmospheric conditions and retarding for the fume corrosion.

The character of pitting under the different conditions is shown by a representative photograph, and attempts have been made to give a quantitative expression to this effect. The amount of metal removed by grinding the samples until pit marks had disappeared was determined and added to the loss by corrosion alone; the value is called the "equivalent corrosion" and is stated as a "pitting factor." Under atmospheric conditions the pitting effect is from 3.5 to 6.5 times that due to rust alone, and the deterioration due to the pitting is therefore materially greater than the effect of corrosion if it were uniformly distributed. Under fume conditions the actual corrosion loss is greater, but the effect of pitting is not so marked and the variation is from 1.7 to 4.0 times the effect of rusting alone, assuming it to be uniformly distributed.

Both papers were discussed together and elicited a long and interesting discussion.

Dr. Cushman thought that conclusions from weighings of the loss by corrosion are misleading. Prof. Palmaer of Stockholm, Sweden, referred to a former investigation made by him on the attack of acids on zinc and the relation of this investigation to corrosion problems. Dr. Walker, Mr. Dewey, Dr. Richardson and a number of other gentlemen also participated in the discussion.

Section on Paints, Drying Oils and Varnishes

At the Wednesday morning session Mr. J. W. Lawrie, of Pullman, Ill., read a paper on Painting Modern Steel Passenger Cars, giving the results of his experience in selecting paints which would serve the double duty of protecting the steel and present the artistic appearance which is demanded in painting these cars. Mr. Lawrie has found the so-called razor blade test accurate when properly carried out.

In general, we can functionate the properties of both the pigment and the vehicle for painting steel.

The pigment must give us the color and shade desired, opacity, thickness of film; it affects the life of the paint, both by its actinic action due to its color absorption, etc., and its chemical effect on the oils or vehicle [illegible] to be such as to give the maximum inhibition of corrosion on the steel.

There is no longer any argument with regard to the preparation of the steel for painting. Wherever possible sandblast. Pickle only when no other means affords itself to remove scale and rust. Pickling with sulphuric acid gives under our usual factory methods the best accelerator of corrosion of any agent met with in regular railway service. Capillary attraction is an extremely powerful force. The sulphuric acid by this force enters the spaces between the crystals of the steel and is held very tenaciously. A mere dipping in a bath of water or several baths of water fails to remove all the acid and with the hydroscopic nature of sulphuric acid an ever increasing area of steel is subjected to acid action. The whole sheet begins to corrode under the paint coat. Even with a paint which is inhibitive and moisture-proof such action will soon destroy these valuable properties.

Artificial Production of Coal.

A Pretty Application of the Law of Reaction Velocity.

In a joint session of Sections II, IIIa, and Xb on Wednesday afternoon, Dr. **F. R. Bergius** presented a very interesting paper on an investigation in which he tried to imitate the processes of Nature in the production of coal.

By employing a high temperature and a high pressure he accomplished in a few hours a result analogous to that produced by Nature in a long time. He heated cellulose at 350 deg. in water in a closed electrically heated furnace until the pressure became 400 atmospheres. Samples were taken from time to time and it was found that the cellulose had been changed to peat (analysis 85 per cent C., 5 per cent H, balance O). The result was obtained in twenty-four hours, no further change being obtained in sixty hours.

By applying the Van't Hoff-Nernst law of reaction velocity, it is found that the same change from cellulose to peat at 10 deg. C. requires 7,000,000 years—a geological period.

Synthetic Rubber

Friendly British-Germany Rivalry.

The lecture by Prof. **W. H. Perkin** on "the polymerization of butadine and isoprene" before the Sections on Organic Chemistry and India Rubber, held on September 11th, in the afternoon, attracted a large audience on account of the great publicity which the author's investigations on synthetic rubber have recently had.

Prof. Perkin outlined the method of making synthetic rubber, which he had recently described in a paper before the Society of Chemical Industry and then described a new method which he said looked very promising. Since this new method has not yet been described we give its outline here as follows:

Take ethyl alcohol, which may be easily oxidized to acetaldehyde. This is condensed by means of potassium carbonate to aldol and the aldol can be quantitatively converted into butylidine glycol. All the yields of these reactions are practically quantitative. The butylidine glycol is then converted into a chloride and passed over soda lime when practically the same product is produced as the isoprene from the isoamyl chloride and when treated with sodium gives even better rubber than isoprene.

Dr. Perkin exhibited samples of what he called the first synthetic rubber ever made (the product of Tilden).

In the discussion Dr. C. Duisberg thought that Dr. Perkin had not yet proved the value of his product. This can only be proved by using the synthetic rubber product in practice, for instance, as an automobile tire; this, he said, they had done with their German synthetic rubber.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Vol. X | New York, October, 1912. | No. 10

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

J. W. Richards, Ph.D., President.
James H. McGraw, Vice-President.
Curtis E. Whittlesey, Treasurer. E. F. Roeber, Secretary.

239 West 39th Street, New York.

Telephone Calls, 4700 Bryant. Cable Address, Metchem, New York.

Western Office, 421 Boston Bldg., Denver, Colo.
European Office, Hastings House, Norfolk St., Strand, London, Eng.

E. F. Roeber, Ph.D., Editor.
H. C. Parmelee, Western Editor.

The Eighth International Congress of Applied Chemistry.

The Eighth International Congress of Applied Chemistry has passed and gone into history, never to be forgotten, we are sure. What an enormous undertaking it was a few figures will show.

There were 4500 members, of which 2173, coming from thirty different countries, attended the Congress and registered, including 254 ladies. Seven hundred and fifty papers were presented, of which 570 were in print before the Congress assembled. Besides the four general lectures by official representatives of different countries there were 117 single section meetings, with an average attendance of 34 per sectional meeting, and 32 joint section meetings, with an average attendance of 183 per meeting. If we leave out of consideration the joint sessions an average attendance of 34 per sectional meeting means that at any time more than 800 out of the 2173 members who had registered were present at one or the other of the meetings of the 24 sections.

To appreciate the meaning of these figures we need a standard of comparison. The International Electrical Congress, held in 1904 in St. Louis, seems particularly appropriate for this purpose, since it is recognized as perhaps the greatest success of international scientific and engineering congresses held in this country in the past. The number of members attending the Electrical Congress was 700 (against 2173 at the Congress of Applied Chemistry). About 160 papers were read (against 750). There were eight sections (against twenty-four). The ratio being 3 to 1 in the numbers of attending members and sections and 5 to 1 in the number of papers in favor of the Congress of Applied Chemistry, its huge magnitude is clearly established.

The enormous scope of the Congress is best indicated by the special fields to which the work of the twenty-four sections was devoted: Analytical chemistry; inorganic chemistry; metallurgy and mining; explosives; silicate industries; organic chemistry; coal tar colors and dyestuffs; industry and chemistry of sugar; india rubber and other plastics; fuels and asphalt; fats, fatty oils and soaps; paints, drying oils and varnishes; starch, cellulose and paper; fermentation; agricultural chemistry; hygiene; pharmaceutical chemistry; bromatology; biochemistry, including pharmacology; photochemistry; electrochemistry; physical chemistry; law and legislation affecting chemical industry; political economy and conservation of natural resources. Clearly every field of human endeavor in which the work of the chemist counts was represented.

The lasting monument is naturally the set of the Transactions of the Congress. Twenty-four volumes were available in print when the Congress opened, which is an achievement which is without parallel, we believe, in the history of international congresses. That it was appreciated is evidenced by the fact that 1313 members withdrew their sets before the Congress was over. It may further be truly said that the

papers in their perplexing variety were throughout of a high character. That chemistry has not yet lost its revolutionary character and that chemical invention is still able to change industries and rearrange the geography of the world was illustrated by such papers as those by Dr. Eyde on the Norwegian industry of fixation of atmospheric nitrogen, by Dr. Bernthsen on the synthesis of ammonia, by Dr. Duisberg and Dr. Perkin on the synthesis of rubber.

The social functions were delightful and every member enjoyed immensely and to the utmost the personal intercourse with so many colleagues and leaders from so many countries. This is, of course, the main reason why people attend an international congress. They can read any paper with greater leisure and convenience later on at home, but only at the Congress are they able to see what kind of a man has written it. The simple privilege of every chemist who attended the Congress to see, hear, and meet congenial men from many countries, to discuss questions of mutual interest with the great leaders in his chosen field—this privilege must have been a source of inspiration the value of which is inestimable. But we think that the uplifting effects of the late Congress will be felt far beyond chemistry. This intermingling of men, coming from many countries, speaking different languages, interested in many different lines of work, must have led to an interchange of ideas on those broad problems in which the citizens of all countries are equally interested as brothers and citizens of the world. We sincerely hope that the late Congress has done more towards friendship and peace between nations than any peace society or any number of battleships can ever do.

Since our whole issue of September 12th and part of the present issue are devoted to reports of the Congress and to abstracts of papers, there is no necessity to go any more into details at this place. But a tribute of appreciation is due here to all who contributed to the success of the Congress, that is, to all its members who joined in serious work and in happy enjoyment of the occasion, to all the members of committees who spent uncounted hours and days of hard and yet pleasant work in the preparation of the Congress, and to its four chief officers: the president, Dr. Wm. H. Nichols, the honorary president, Dr. Edward W. Morley, the treasurer, Mr. W. J. Matheson, and the secretary, Dr. Bernhard C. Hesse. Through their indefatigable energy and the combined efforts of all, the Eighth International Congress of Applied Chemistry was made a success of which American chemistry and this whole country may well be proud.

Advances in the Metallurgy of Aluminium.

That the laws of supply and demand govern chemical and metallurgical invention as well as any other field of human endeavor, is well illustrated by the present activity in the metallurgy of aluminium. The demand for aluminium is increasing enormously. Dr. Heroult remarked last year in his delightful little speech on the occasion of the award of the Perkin medal to Dr. Hall: "Aluminium is wedging its way in the metal market. It looks probable that in a course of ten or fifteen years the consumption of the new metal will be equal to that of copper and that after the golden age, the stone age, the bronze age, and the iron age, we may have the aluminium age." The demand is clearly not only for more, but for cheaper aluminium, and chemical invention will supply it.

Besides a new alumina process of a distinguished American chemist, which is now about to be tried out on a sufficiently large scale, but is being carefully kept secret for the present, the Serpek process, in use on a large experimental scale in a plant in France, looms prominent. As is well known, with aluminium nitride as an intermediate product, it yields pure alumina and ammonium sulphate. It is, therefore, technically an interesting combination of the production of pure alumina for aluminium manufacture with the fixation of atmospheric nitrogen. Commercially it may be said that the Serpek process is now in a decidedly "interesting condition."

And now, on the last day of the International Congress of Applied Chemistry, Mr. Alfred H. Cowles, the distinguished pioneer of electrochemistry who needs no further introduction to our readers, announced for the first time in public the principles of the new Kayser-Cowles process which is to be operated in a plant at Sewaren, N. J. It is an ingenious and ambitious process yielding aluminium, hydrochloric acid, caustic alkali, and white hydraulic cement from clay, salt and lime. The process certainly appears sound chemically, and it may be hoped that any chemical engineering difficulties which may turn up, as they always do in the introduction of a new process into operation on a large scale, will be overcome as a matter of course. Mr. Cowles' most interesting paper is published, practically in full, in this issue.

Altogether the metallurgy of aluminium is at present full of promise of almost revolutionary developments and deserves close watching.

Methods of Sampling and Analysis.

There is something to be said both for and against the policy of "standardizing" methods of technical procedure, such as the sampling and analysis of ores and metallurgical products. The opponents of the idea usually contend that the very act of adopting a standard method is a bar to progress, and removes the incentive to research for better methods; that a standard method once promulgated as such by some authority is likely to gain a strong position, and be retained in spite of possible deficiencies. However much opinions may differ on this subject, we believe that even the opponents of the policy must recognize the fact that the prevailing industrial conditions of the day warrant an attempt to have the best methods uniformly adopted, with no implication that these may not be changed from time to time.

In fact it may be said that the present need for uniform methods is the result of research, and that when a method is proposed for uniform adoption it represents the best that has been evolved from the experience of many competent men. Instances could be multiplied to show the impossibility of two analysts producing concordant results on the same material without following practically the same methods of sampling and analysis. Hence the commercial need for uniformity. The demand becomes more insistent when a large company employs a number of chemists situated at different places, and all working on the same materials. It is scarcely less imperative among individual companies buying each other's products. Business is expedited because reliance can be placed in accurate results.

Elsewhere in this issue we publish the methods of the United States Steel Corporation for the commercial sampling and analysis of pig iron, prepared by the chemists' committee of that corporation and presented in form of a paper before the Eighth International Congress of Applied Chemistry. This is the third of the excellent reports which have emanated from the same source. The first, which we published in February, 1909, dealt with the commercial sampling and analysis of iron ores. The second, which appeared in our issues for June and July, 1911, outlined methods for the technical sampling and analysis of gases. They resulted from a condition already mentioned, namely, that prior to their adoption a number of men were carrying on the sampling and analysis of these materials under varying conditions with consequent non-conformity in results. By careful consideration of the methods used in each laboratory under the corporation's control, general methods were evolved which undoubtedly are preferable to some that were used before. In this way the standard of all the work has been raised.

In addition to the reports already published by the Chemists' Committee of the Steel Corporation, methods of sampling and analysing steel, ferro-alloys, etc., are being investigated and will be issued in due time, when we hope to publish them in this journal. The complete series will form a most valuable critical compilation of useful methods based on extended research and wide experience.

The Steel Production Statistics.

The American Iron and Steel Institute reports production of steel ingots and castings and of rolled iron and steel in the first half of 1912 as follows, the figures representing gross tons:

Basic open-hearth steel	8,927,579
Acid open-hearth steel	514,127
Bessemer steel	4,868,306
Crucible steel	53,476
Electric steel	6,882
Miscellaneous steel	3,331
Total steel	14,373,701
Steel castings, included above	490,218
Rolled iron	779,481
Rolled steel	10,422,338
Total rolled material	11,201,819

The Institute succeeds the American Iron and Steel Association in the gathering of American production statistics. Under the management of Mr. James M. Swank, the Association has gathered these statistics for forty years, Mr. Swank's first work having been the gathering of 1872 statistics, early in 1873. The Association has gathered pig iron production statistics semi-annually, and all other statistics annully, and its work closes with the presentation of full statistics for the year 1911, and of pig iron statistics for the first half of the present year. The Institute at once esablishes a new practice, of gathering steel statistics for semi-annual periods, and for this departure it is much to be commended. A curious fact is that the statistics for several items are presented for the first half of 1912 when the Association has not yet published the corresponding statistics for 1911, and one is curious to know how it is that the Institute shows more promptness in its maiden effort than the Association does after forty years of experience. The Association's figures have established such a reputation for accuracy, being admittedly much better in point of accuracy and completeness than those of any other iron and steel producing country, and it may perhaps not be amiss to suggest that the trade would welcome a positive assurance from the Institute management that the Association's standard of accuracy has been maintained.

The production of steel in the first half of this year cannot be compared with previous records, because half-yearly statistics of steel production have not hitherto been gathered. It is well known, however, that the most active period in the past was the first half of 1910, and if that half year produced the same proportion of the year's total steel production as obtained in the case of pig iron—for which semi-annual statistics are available—the output was approximately 14,400,000 tons of steel ingots and castings, substantially the same quantity as now reported for the first half of this year. A new record has not been made, therefore, at least by any considerable margin. The present half year, of course, is easily making a new record, as production is at a much greater rate than in the first half of the year.

A new tonnage record for basic open-hearth steel was made in the first half of this year, for the basic open-hearth steel production was 62.1 per cent of the total steel output, and exceeded that of Bessemer steel by 84 per cent, whereas in 1910 basic open-hearth steel was only 58.7 per cent of total steel, and exceeded Bessemer steel by only 64 per cent. The decadence of the Bessemer steel process, not merely relatively, but also absolutely, is further assured, for the record tonnage year in Bessemer steel was as far back as 1906, with 12,275,830 tons, and the production in the first half of this year was only 4,868,306 tons. No new Bessemer steel plant has been built since that of the Youngstown Sheet & Tube Company, which made its first steel in the summer of 1906, whereas two very important Bessemer departments, those of the Carnegie Steel Company at Homestead and Duquesne respectively, have not made Bessemer steel since 1907.

The production of steel ingots, disregarding castings, in the first half of 1912, is reported at 13,883,483 tons, while the production of rolled steel, in the form of rails, wire rods, plates, shapes, sheets, merchant mill products, skelp, etc., is given at 10,422,338 tons, representing an apparent loss of 25 per cent. This is slightly in excess of the average apparent loss in recent years, and suggests the possibility that in some cases the mills have grown more liberal in cropping, when in most cases the basic open-hearth steel furnace stands ready to remelt the material. In discussions of the progress of the steel industry in the matter of tonnage production, it is customary to refer to these statistics of the production of steel ingots and castings as representing "the production of steel." In one sense this is steel production, but the more accurate viewpoint is to regard the production of rolled steel, which is actual commercial material. A large part of the ingot material merely passes over the ingot scales, and passes not into the steel market, but into the open-hearth steel furnace, to be melted and pass a second time over the ingot scale.

Old Freibergers in America.

A very enjoyable and enthusiastic meeting of old students of the Freiberg Bergakademie was held at the Hofbrau Haus, Broadway and Thirtieth Street, New York City, on Friday, September 13.

At this meeting it was unanimously decided to arrange for a dinner in New York City near the Christmas holidays and at that time form a permanent organization.

Among those present at the first meeting were: Dr. F. Heberlein, of Frankfort, a/M., and Prof. R. Hoffmann, Professor of Metallurgy at the Clausthal School of Mines, Clausthal, Germany. Both of these gentlemen are well known not only as old Freibergers but as highly distinguished metallurgists.

The organizers are having some trouble in getting correct addresses, since mining and metallurgical men are a wandering crowd.

All old Freibergers are, therefore, asked to send in their names and addresses, with others they may know of, to Mr. C. L. Bryden, 1015 Myrtle Street, Scranton, Pa., so that a notice of the next meeting can be mailed to them.

The Iron and Steel Market.

In specifications for finished steel products filed with the mills September has shown no improvement over August, as normally it should on account of the season, but the heavy specifying in July and August was altogether abnormal. September has fully maintained the pace of August, showing specifications in excess of current shipments, so that the mills have a somewhat larger volume of actual specifications on their books than at the close of August and a much larger volume than at the close of July. As tonnage taken at lower prices is being constantly worked out, the average realized price on shipments is constantly increasing, giving the mills better profits, although profits are still relatively small.

Production of steel continues to be at the maximum capacity of mills, and is somewhat improved over the summer months on account of weather conditions. The labor supply is no better, and hampers operations in many minor ways. The car supply is also a serious problem, and while the current make is being shipped, the shipments are maintained only by the exercise of constant vigilance, and conditions are certain to be worse in October and November on account of the drain for moving the crops.

It has become the regular practice with many mills to make minor repairs on box cars at their own expense, to render them weatherproof.

In this way many cars have been made available which otherwise could not be used.

Early in September the independent sheet and tin plate mills began advancing prices, and the leading interest concurred, establishing black and galvanized sheets and tin plate on a higher basis, black sheets being advanced from 2.05 to 2.15 cents, galvanized sheets from 3.15 to 3.30 cents and tin plates from $3.50 to $3.60. The increased spread between black and galvanized sheets is to be noted, 1.15 cents per pound on No. 28 gage.

This increase was due to spelter having a record high price, about 7½ cents, East St. Louis. As large a spread between black and galvanized has sometimes prevailed in the past, with lower spelter prices, and the present spread is not regarded as sufficient.

During the month several mills announced advances of $1 a ton in bars, plates and shapes, applicable to first quarter business, and making the advanced prices 1.35 cents for bars and 1.45 cents for plates and shapes. In harmony with a policy recently adopted, of curbing the advancing tendency in the steel market, the United States Steel Corporation did not follow this lead, but is selling these products in a limited way for next year at the old prices. On account of the mills being so well sold up there is room for a variety of prices in the market.

While the selling of bars, plates and shapes to ordinary buyers for the first quarter has not been large, the market has been definitely opened in sheets and tin plates. The leading interest formally opened its books on Monday, Sept. 23, for sheet orders from jobbers and ordinary manufacturing consumers, and at the same time for tin plate orders from ordinary buyers for first quarter, but from makers of packers' cans for the regular season. The opening is an early one in both sheets and tin plates, but was practically forced by the peculiar conditions, the mills being practically sold up for this year. In both sheets and tin plates they have actual specifications for about half the prospective make in the remainder of the year, and as specifications are coming in very freely on unexpired contracts they are certain of full operations throughout the year without the booking of additional contracts.

The finished steel market is thus gradually opening for the new year, and with pressure on the mills for deliveries even heavier than it was there is less occasion to fear that the advent of the new year, with the expiration of many low-priced contracts, would see a lull in buying activity. While buyers will have to pay materially higher prices for next year's materials, the momentum acquired will probably carry the market into the new year without a jar.

Pig Iron.

Pig iron prices in all districts have been advancing almost spectacularly, considering the slowness with which they advanced for many months when conditions in the steel trade were all extremely favorable. The somewhat sudden change in the aspect was due to several causes. In the first place, large stocks of merchant pig iron had accumulated in 1910, after the ill-advised boom in 1909, and these were not well liquidated until about the middle of this year. In the second place, the Connellsville coke operators became seized last May with the idea that they should secure a large advance in coke, about $1 a ton, even though prices for pig iron obtained by their customers did not justify such an advance. They held that a coke advance should force a pig iron advance, which is not the customary procedure. The furnaces, as a rule, were disposed to hold pig iron prices down until the coke operators were willing to accept lower prices. The deadlock was broken late in July, operators accepting $2.25 and possibly less when they had been holding out for $2.50. Under strictly open market conditions, however, the coke market has since advanced to $2.50 or higher. Finally, the merchant furnaces in operation, being quite well sold up, were averse to seeing a paper advance which would benefit them little and would presumably attract many idle furnaces into the active list. The position is now worked out. The stocks are disposed of, coke is selling under open market conditions at a high price, and furnaces are ready to sell for next year, while there is no longer hope of discouraging idle furnaces from blowing in. Pig iron in the past month has advanced sharply in all districts, with fairly heavy selling for delivery in the first quarter of the new year. We quote: Bessemer, $16; basic, $15; No. 2 foundry, $14.75@$15, f.o.b. valley furnaces, 90 cents higher delivered Pittsburgh: No. 2X, delivered Philadelphia, $16.50; No. 2 foundry, delivered Chicago, $17; No. 2 foundry, Birmingham, $13 to $13.50.

Steel.

Unfinished steel has become extremely scarce for any delivery this year, and mills are not naming prices for next year. As representing nominally the general level, we quote, f.o.b. maker's mill, Pittsburgh or Youngstown: Bessemer billets, $23.50 to $24; sheet bars, $24; open-hearth billets, $24.50 to $25; sheet bars, $25.50; rods, $26.50 to $27.

Finished Steel.

Current prices, f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.40 to 1.45 cents.

Shapes, 1.40 to 1.45 cents.

Steel bars, 1.30 to 1.35 cents.

Common iron bars, 1.50 cents, Pittsburgh; 1.45 to 1.50 cents, Chicago; 1.45 cents, Philadelphia.

Steel hoops, 1.50 cents.

Sheets, blue annealed, 10 gage, 1.55 to 1.60 cents; black, 28 gage, 2.15 cents; galvanized, 28 gage, 3.30 cents; galvanized corrugated, 3.35 cents.

Tin plates, $3.60 for 100-lb. cokes.

Merchant steel pipe, 79 per cent off list.

Steel boiler tubes, 3½ to 4½ in., 73 per cent off list.

Standard railroad spikes, 1.80 cents.

The Western Metallurgical Field.

Concentrating Low-Grade Silver-Lead Ore at Aspen, Col. One of the most difficult tasks in profitably concentrating low-grade ore is that undertaken by the Smuggler Leasing Company, in an effort to revive the famous old mining district

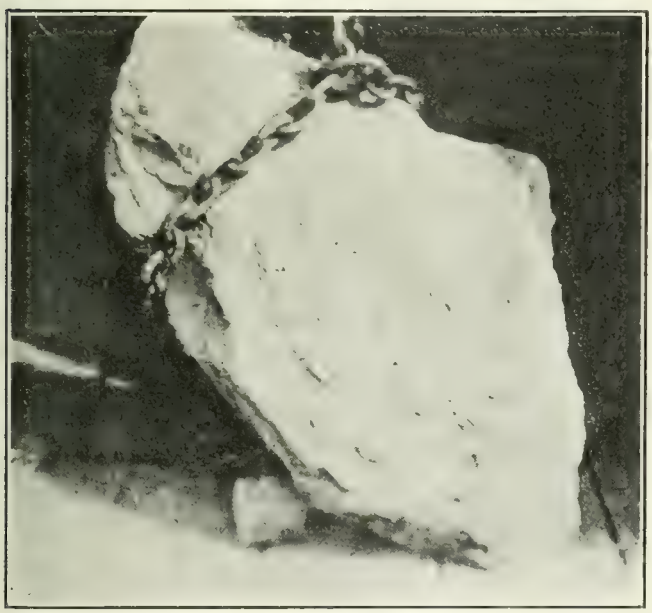

FIG. 1.—LARGE SILVER NUGGET FROM SMUGGLER MINE, ASPEN, COL.

of Aspen, Col. Prior to 1893-4 Aspen was one of the remarkable silver producers of the West. The Smuggler, Mollie Gibson, Aspen and Durant mines were well known for their production of native silver and high-grade silver-bearing galena. Silver nuggets of great size and value were not of uncommon occurrence, and rich pockets of ore were opened frequently. In the accompanying photograph is shown the largest silver nugget known, which was taken from the Smuggler mine. It weighed 1840 lb. and was of a fineness equal to that of sterling silver.

Conditions at Aspen have changed, however, since the bonanza days. The price of silver is greatly reduced; the grade of the remaining ore is very low; the expense of pumping and timbering is heavy; and altogether the situation demands the most careful management. A large tonnage of ore must be handled and prospecting for new deposits must go hand in hand with production. It is worthy of mention that those who are responsible for the operations of the Smuggler Leasing Company are men who formerly realized great wealth from the old mines, and who still believe that there is more money to be made by properly treating the low-grade ore. There is also the ever-present hope that bodies of rich ore may be opened in the course of development.

The Smuggler mill is an old structure of German design, and still contains some of the German machinery, notably the jigs. As originally designed, a great deal of manual labor was required in shoveling and tramming concentrates, and in elevating the crushed crude ore on platform elevators. These features have been displaced, of course, by suitable launders and elevators. The original capacity was 125 tons per day, but by remodeling this has been increased to 350 tons.

The concentrating ore is argentiferous galena in a gangue of limestone and quartz. The mineral is fine-grained and requires regrinding to liberate the smallest crystals, thus creating a large amount of slime. Further, the gangue is soft and slimes badly in crushing, and as the lime carries silver the recovery of this metal is made increasingly difficult. By a local custom the grade of the ore is stated in "points," each per cent of lead and each ounce of silver per ton being a "point." Thus, "12-point" ore contains, say 10 per cent lead and 2 ounces silver per ton. The average grade of ore being milled at this time is about as given. The recovery of lead will average about 85 per cent, but silver loss is high and only 60 per cent of the silver is recovered.

It is the aim of the concentrating process to enrich this ore to an average grade of at least 15 to 16 per cent lead and 4 to 5 oz. silver per ton, or in the local vernacular, 20 points, as this is the lower limit of profitable grade of concentrate. Frequently the grade will average 18 per cent lead and 5 oz. silver per ton for a period of a month. This, of course, represents mixed coarse and fine concentrates, the former being higher grade and the latter lower than the average.

It is estimated that the company can treat its low-grade ore at good profit if the mill handles 350 tons per day of ore containing 10 per cent lead and 2 oz. silver per ton. But the capacity of the regrinding division is not equal to that of the coarse concentrating department, hence at present the latter is run only two shifts per day and the former three shifts.

Following is an outline of the concentrating system. Bottom-dump railroad cars convey the ore from the mine to the mill and discharge into a hopper beneath the tracks. From here the ore is conveyed to the crushing department by an inclined link-belt conveyor. A shaking feeder, punched with 1-in. holes, delivers the oversize to the crusher. Concentration begins at 16 mm. in a Harz jig, where about 8 per cent of the original mill feed is removed. Jigging is continued on the following sizes, 12, 8, 6, 4½ and 3 mm., and on the two coarse products from hydraulic classification of the undersize of the last (3 mm.) screen. Three Wilfley tables treat the balance of the classified material, completing the coarse concentration.

In the regrinding division the middlings from the jigs are ground to 20-mesh in Huntington mills. Ton-cap and rek-tang screens are being tested in these mills. Wilfley tables, smooth and corrugated belt vanners are used here, the concentrates being conveyed to central elevators by shaking launders. An extensive system of settling boxes is provided to recover mineral slime which flows away from the various machines. The material thus recovered contains from 15 to 18 per cent lead and is mixed with the coarser concentrates.

Mention has been made of the old jigs originally installed and still in use. These have a crank-arm mechanism to control the plunger stroke, which is seldom used in modern jigs. The object of the mechanism is to impart a quick pulsion and slow suction to the bed of ore on the screen, so that after each downward stroke of the plunger the ore bed would be free to settle in nearly still water. The expense of maintaining these jigs has been found excessive, especially where the old construction of a sectional shaft is still used.

Mr. Walter W. Davis, of Leadville, is manager for the Smuggler Leasing Company, being represented locally by Mr.

Guy Newton. Milling operations are under the direction of Mr. W. H. Cornwall.

Company Reports

The report of the **Ray Consolidated Copper Company** for the second quarter of 1912 shows that the total amount of ore treated for the second quarter was 374,609 tons, as compared with 301,674 tons. The average grade of the ore for the quarter was 1.72 per cent copper, almost exactly the same as for the first quarter. The average recovery for the quarter was 69.37 per cent; the average for the previous quarter was 68.85 per cent. The recovery in pounds, per ton of ore, was 23.9 as compared with 23.6 lb. for the preceding quarter. The net tonnage and average grade of concentrates produced was 22,879.51 tons containing 19.563 per cent copper, as against 17,637 tons for the first quarter containing an average of 20.19 per cent copper. The average cost per pound of net copper produced for the quarter, after making allowances for the smelter deductions, was 9.954 cents. This cost was 10.19 cents for the preceding quarter.

In comparing the cost for the second quarter with those of the first, it should be noted that during the second quarter slightly over half a cent per pound of copper produced was charged to create a fund to extinguish development expense, which charge was not made in the first quarter.

The improvement in operating and production costs, as tonnage is increased, is well indicated by the fact that during the month of June the cost per pound of copper derived, as above stated, was 8.95 cents per pound.

During the quarter, five sections of the Hayden plant were available for continuous operation, but for a large portion of the time it was only necessary to use four of them to accommodate the tonnage produced at the mines. Toward the end of the quarter the five sections were in continuous operation. The sixth section has been finished and is ready for use as required. Construction work on the seventh section is progressing at such a rate as will insure its completion when needed which will probably not be before the first of October. The cost of milling for the quarter, including a proper apportionment of all general and fixed charges and expense of every nature, was 45.52 cents per ton, as compared with 56.07 cents for the first quarter. The mill, power plant, water system and all other accessories are operating in a thoroughly systematic and satisfactory manner.

The smelter of the American Smelting and Refining Company, at Hayden, has been in continuous operation since early in May, handling concentrates as produced with one reverberatory furnace. The concentrates are proving admirably adapted to direct smelting without admixture of other ores or fluxes, except the usual quantity of lime, and are therefore taking the base smelting charge without any penalties whatever for refractory qualities.

Steady improvement is shown in the operations of the **Chino Copper Company,** as published in the report for the second quarter of 1912.

The total amount of ore treated for the quarter was 167,025 tons as compared with 160,400 tons for the preceding quarter. The average grade of the ore treated for the period was 2.04 per cent copper. The production of concentrates amounted to 9035 tons, containing 23.74 per cent copper, as compared with 8048 tons of concentrates containing an average of 20.33 per cent copper for the preceding quarter. The average recovery for the quarter was 62.96 per cent, corresponding to 23.74 lb. of copper per ton of ore treated, as compared with a recovery of 20.4 lb. for the preceding quarter.

In our last report it was explained that the low recoveries were due to the large amount of oxidized copper minerals existing in the ores then being mined. This condition continued to a considerable extent throughout the first two months of the quarter under discussion. By the first of June, however, a better quality of ore was available as deeper levels in the steam shovel pits were reached, and for the month of June the average recovery amounted to over 71 per cent of the copper contained in the ores milled.

The average cost per pound of copper produced during the quarter after deduction of smelter allowances, but without crediting miscellaneous income, was 8.02 cents as compared with 7.68 cents for the preceding quarter. The actual cost per pound of direct operations was substantially lower for the second quarter than for the first, but at the beginning of the second quarter a charge was established of 30 cents per ton of ore mined to create a fund for the retirement of development and stripping expense. This charge amounted for the quarter to over 1.3 cents per pound of net copper produced, and the direct operating cost of production for the second quarter was accordingly about 1 cent a pound less than for the first quarter.

Two sections of the plant at Hurley were in continuous operation throughout the quarter, barring ordinary delays. The third section was ready for operation about the first of April, but for various reasons, only two sections, as above stated, could be operated continuously. During the month of April and part of May the water supply was insufficient to operate more than two sections on account of delays in completing the permanent water system. During the month of May some difficulty and delay were experienced in the fine crushing department in treating the first ores mined from the Hearst section. This was due to their clayey nature, which resulted in their retaining a very high percentage of moisture, rendering fine screening difficult and necessitating some changes in the screening plant in the fine crushing department.

During the month of June temporary labor disturbances at the mine were responsible for some shortage in ore supply, and for this reason it was not until after the close of the quarter that three sections could be operated regularly.

Final results for July operations are not available at the time of writing this report, but for that month an average of over 3000 tons daily has been treated with two sections running continuously and a third only a part of the time. The grade of ore has increased somewhat as compared with the second quarter's results and the estimated extraction for the month is above 72 per cent, which is excellent in view of the fact that the ores still contain a considerable quantity of oxidized copper minerals difficult of recovery. The grade of concentrates is increasing with the improvement in quality of the ore. For the month of June the average was about 26 per cent and for July the concentrates will contain over 30 per cent copper. This is an important factor in the reduction of per pound costs for transportation and smelting of concentrates. The production for July, with three sections only in operation, will be more than double that of any preceding month, or well above 3,000,000 lb.

The fourth section of the mill was practically completed at the time of writing this report, and was put into commission about the 15th of August, and it is not probable that the four sections then in commission can be operated at their full tonnage until late in September. The fifth and last section will be completed about the end of September and it is expected that mining and transportation capacities and facilities will have reached a stage where the estimated capacity of 5000 tons per day for the plant can be supplied in October. Under favorable conditions the concentrator has developed a capacity of nearly 1500 tons per section and it is certain, therefore, that the completed plant will be able to mill considerably in excess of 5000 tons per day for which it was designed.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in May, 1912, was 61. The total quantity of ore milled during that period was 2,227,532 tons. There were 10,073 stamps in operation with an average duty of 8.21 tons per 24 hours. Tube mills in commission numbered 266. The yield for the month was 779,662 fine ounces gold.

Notes on Chemistry and Metallurgy in Great Britain.

(From our Special Correspondent.)

Peat as a Source of Power.

At the summer conference of the Institution of Mechanical Engineers at Belfast, Mr. **H. V. Pegg** presented a paper on the "Commercial Utilization of Peat for Power Purposes." The author arrived at the conclusion that, in view of the generally poor results obtained by means of costly plant for preparing peat, the employment of peat on a commercial basis depended on its being used as nearly as possible in the state in which it was cut from the bog lands. Preliminary experiments, some seven years back, with air-dried peat in a special gas producer, showed that the extraction of the tar from the gas was preferable to attempting to make gas of it, and that the producer must be comparatively unaffected by the amount of moisture in the peat.

About two years ago some tests with experimental plant at the works of Messrs. Crossley Bros., Openshaw, resulted in that firm making a special producer plant with which, in October, 1911, a six hours test run at a load of 250 B.h.p., using peat containing 18.98 per cent of moisture, gave an average consumption of 2.55 lb. of peat per B.h.p. hour. The peat used during November and December was very wet; its moisture varied very much; and, although not exactly determined, was estimated at quite 70 per cent; yet the plant worked quite as well with this as with the drier peat, but of course the consumption was proportionately greater.

For the removal of tar from the gas—which was the chief difficulty—an ample water spray was found superior to coke scrubbers as these soon became clogged. Most of the tar was thrown out by a centrifugal-extractor; but unless the gas were sufficiently washed and cooled by plentiful water spraying some tar passed by the extractor, deposited in the gas mains, and ultimately entered the gas engines.

The plant now in use was capable of being run for three weeks without being cleaned, although as a matter of precaution it was usually cleansed weekly; and the amount of wash water had been increased to 7 gal. per B.h.p. per hour. The tar recovered was about 5 per cent of the weight of fuel used, and at first some of the tar was sold at 35/- per ton; but its persistent pyroligneous odor, which also clung to all the oils distilled from it, stopped the sale. The tar contained up to 50 per cent of water and much solid matter.

At present the whole of the factory at Portadown was being run on peat fuel exclusively with a total consumption of about 44 tons per week, about half of this amount being used in the producer plant; but the consumption varied with the kind of peat from 35 tons of good black fuel to 54 tons for light surface peat. From figures furnished by the works manager, the cost of the peat fuel showed a saving of £15-5-6 per week after allowing 15/- per week for extra labor, thus: 8½ tons of anthracite at 35/- and 19 tons steam coal at 17/ = £31-0-6; against 50 tons of peat at 6/- = £15-0-0.

French Aluminium.

An association of French manufacturers under the title of "L'Aluminium Français" has secured the patent rights for all the world of the Serpek process of manufacturing aluminium: and, according to a British Consular report from Lyons, is proceeding to erect extensive works with a 40,000-hp equipment. It is proposed to put down the rolling plant near Chambéry, in the expectation that the ample water power obtainable will result in very considerable saving in working costs.

The association acquired the patent rights from the Société des Nitrures, who in turn derived them from the Swiss holders and conducted manufacturing operations on an experimental scale in the neighborhood of St. Jean de Maurienne. The rights for the United States have been disposed of to a subsidiary company (which is erecting a plant in North Carolina, as noticed in our July issue, page 445), but at present there is not any mention of the process being taken up by British manufacturers.

Electrolytic Hypochlorite.

The medical officer of health for the Borough of Poplar, Dr. **F. W. Alexander,** has recently issued his annual report for 1911, which gives particulars of the production and employment of hypochlorite during the last six years. Since the plant was first put down about 200,000 gal. of solution, containing an average of 5 gr. of available chlorine per litre, have been produced at a total cost for materials of rather less than £380; and the output for 1911 was 53,063 gal. at a cost of £108-9-0 for materials and electricity.

The use of the fluid in the public baths of the borough has been continued at the rate of one part of chlorine to 2,000,000 parts of water, and the bath superintendents report that this addition is perfectly effective in preventing formation of slime in the water, that no slime is found at the bottom, nor is there any offensive smell when the baths are emptied for cleaning.

In the Public Health Department the fluid has for some years entirely displaced carbolic disinfectants, and it is also exclusively used at the institutions of the managers of the sick asylums and of the Board of Guardians. The number of rooms disinfected during the year was 1626, and the articles of bedding, clothing, etc., totalled 41,143. Dr. Alexander deals with the contention that hypochlorite could be produced more cheaply by lixiviation of bleaching powder, by pointing out that the price of this substance fluctuates considerably, that the powder deteriorates rapidly on exposure to air, that the lime residues would be a nuisance, and that the cost of supervision and labor would be increased; and he points out that it is much easier to work out figures on paper than to practically produce results.

The fluid made at Poplar is termed "hypochlorite of magnesia," but the report shows that the materials used for the last year's working include over 8 tons of sodium chloride, and a ton or more of caustic soda, in addition to about 5¾ tons of magnesium chloride.

The Iron and Steel Institute.

The autumn meeting of the Iron and Steel Institute will be held at Leeds on September 30, and the four following days. Among the papers submitted are the following:

"On Nitrogen and Iron," by J. H. Andrew; "On the Solubility of Cementite in Hardenite," by Dr. Arnold and L. Aitchison; "On the Solubility or Diffusion of Hardenite in Ferrite," by Dr. Arnold and C. Chappell; "On the Gases Evolved on Heating Steel to Its Melting Point in a Vacuum," by G. Wesley Austin; "On Allotropy in Genera', and That of Iron in Particular," by Dr. C. Benedicks; "On a new Type and Method of Construction of Large Gas Engines," by A. E. L. Chorlton; "On the Thermal-magnetic Transformations of 25 per cent Nickel Steel," by Dr. Colver-Glauert and Dr. Hilpert; "On a Method of Producing Sound Ingots," and "On a New Method of Revealing Segregation in Steel Ingots," by Sir Robert Hadfield; "On the Magnetic Properties of Manganese and Nickel Steels," by Dr. Hilpert and Dr. Mathesius; "On Steel Works Yields," by P. Longmuir and W. H. Robinson; "On Rolling Mill Practice in the United States," by Dr. J. Puppe, and "On the Growth of Cast Irons after Repeated Heatings," by Prof. H. F. Rugan.

The British Association.

The Dundee meeting of the British Association will open on September 4, when the new President, Mr. **E. A. Schäfer,** F.R.S., will deliver his address on "The Nature, Origin and Maintenance of Life." A joint meeting of the Botanical and Zoological sections will also consider the question of the origin of life, and Professor Minchin (London) will give an account of his experiments in the fertilization of some lower forms of marine life. Professor A. Senier will preside over the chemical section and Professor A. Barr over the engineering section.

Market Prices.

August, 1912.

Tin opened at 204, dropped £2 during the first two days, recovered on the 7th and since rising, had reached 212 by the 20th, afterwards declining to 210, but better on 30th at 212-10s.

Copper fairly steady, opened at 78, and kept within £1 till the fourth week, when it had risen over £79, reaching £79-10, by the 28th. Closes at £78-15.

Hematite has been rising. Opening at 75/- it was 78/- on the 7th, 77/- on the 20th, closes at 77/9.

Cleveland has also been strong. Opened at 59/-, reached 60/- by 13th, 61/11 by the 22d, 62/9 by the 24th, and closes at 63/7.

Scotch Pig has followed the same upward movement. Opened 65/-, reached 66/- on 14th and closed at 67/7.

Lead was £19-15 on the 9th, and £20 on the 22d, making 20-5 by the 24th, and £20-10 to £21 by the 28th, closing at 21.2.6.

India rubber. Para fine. Has been fairly steady, with rise during last few days. Closes at 5/1.

CORRESPONDENCE.

Function of Slag in Steel Refining.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—The paper by Dr. Amberg in your September 12th issue on "The Function of Slag in Electric Steel Refining" is very interesting, since it touches on a subject which is of great importance and of which we still know relatively little.

The primary function of slag in an electric steel refining furnace is to remove the impurities—phosphorus, sulphur, oxygen, and, where desirable, manganese and silicon. In present practice the actual function of the "first" slag is practically the same as for an ordinary basic open-hearth slag. This fact is pointed out by Dr. Amberg in his interesting paper and this function might be called the "oxidizing slag function" in contrast with the "reducing slag function."

In view of the primary difference between an electric furnace and a combustion-heated furnace, making possible the complete control of the conditions in the electric furnace, it should be possible to give the refining slag a greater variety of functions in the electric furnace than in a combustion-heated furnace, and the slag should not only take up the given impurity, or several impurities, but should do this quickly and economically and without any detrimental action on the metal. That is, it should not leave the metal in such a state as to require further refining to correct the bad effect of the first slag.

In the present operation of electric furnaces a second slag is essential to correct the bad effects—namely, the over-oxidation resulting from the first slag.

What the writer wishes to point out is that in order to fulfill the functions of an ideal slag the conditions in the furnace must be neither extremely oxidizing so as to require corrective effect later nor extremely reducing so as to reduce the impurities back into the metal.

The slag may, of course, be used first as a carrier of oxygen as well as a fluxing agent for the impurity, but when this additional oxidizing function is required of the slag, some other of its functions—namely, its reducing action—is necessarily limited thereby, and usually made inoperative. Furthermore, the oxidizing action of a slag should be slower than the oxidizing action of a gas blown into the metal. In the latter case where the gaseous oxidizing agent is used it is possible to more nearly reach the conditions of an ideal slag, in which the slag acts purely as a collecting and holding agent—that is, a fluxing agent for the impurities without injurious effect on the metal.

Dr. Amberg refers to the use of carbon and silicon as the reducing agents for reducing the slag and deoxidizing the metal. From the writer's experience it has been found that a gaseous agent can be used to reduce oxides of iron without reduction of calcium phosphate, and the tests referred to in Dr. Amberg's article of using solid carbon to deoxidize a phosphate slag without reducing the phosphorus back into the metal have, so far as the writer knows, proved a failure. The use of a gas, however, can accomplish this result. An ordinary producer gas with six or eight per cent of CO_2 will serve to reduce the iron oxides out of a phosphate slag without reducing the calcium phosphate therein, and at the same time will permit that slag to take up and hold sulphur from the metal.

Chicago, Ill. ALBERT E. GREENE.

* * *

To the Editor of Metallurgical and Chemical Engineering:

Sir:—It is to be regretted that as Mr. Greene was not present at the meeting of the Congress he could not contribute the interesting remarks on his process of deoxidizing by gases to the general discussion. As I have not had any practical experience with it I could not deal with it in my paper.

The process of Ernest Humbert to which Mr. Greene seems to refer implicitly has apparently proven a failure in the instance which Mr. Greene knows of, but it is giving excellent results right along in many other cases when properly carried out.

I would by all means keep the CO_2 of an "ordinary producer gas" below 6 per cent. This would mean that the Greene process necessitates a special producer and an independent gas main, viz., increased cost of installation.

Harrison, N. J. RICHARD AMBERG.

Electric Steel Refining.

To the Editor of Metallurgical and Chemical Engineering:

Sir: Referring to your note regarding the Bethlehem Steel Company, on page 509, of your September issue, we should like to say, merely in order that there be no mistake, that Friedr. Krupp, of Essen, Germany, also has one other electric steel furnace besides the one you mention. They have a Frick induction furnace, which has been in operation for making high-quality special steels for the past three years. These special steels embrace not only the various tool steels, but also those used for high-quality forgings and castings. In addition it is used for melting ferro-manganese; its use in the molten state instead of its usual solid form, permits a saving of at least one-third of this alloy, when added to the Bessemer process steel. As for electric steel rails, these have been in operation in Germany for four years past in all sorts of weather and temperatures and have proven to be unbreakable in service.

K. G. FRANK,

The Power Required for Refrigeration.

By John J. Smith.

The use of artificial refrigeration for industrial purposes has increased to a great extent in the last two decades, and with the development of chemical industries of various kinds, is undoubtedly destined to increase much further.

Under these circumstances it is very necessary for those interested in such industries to know what the cost of such refrigeration will be, or, at least, what power it will require.

Engineers are very generally accustomed to thinking and calculating in units of horsepower, but relatively few of them are sufficiently familiar with refrigeration to be able to calculate, from the refrigeration required, the horsepower necessary. It is to supply, at least in part, this deficiency that the present article is written.

In the year 1906 the Iron and Steel Institute of Great Britain published a paper by J. E. Johnson, Jr., on which the present article is founded. This paper pointed out the connection as shown by thermodynamics between the quantity of refrigeration, the temperatures involved and the theoretical horsepower required, and then gave a method for determining the factor by which the latter must be multiplied to give the actual horsepower needed, based on the best data then available, notably the publications of Professor J. E. Denton, on that subject.

Within quite recent years, however, the York Manufacturing Company, under the guidance of its General Manager, Mr. Thomas Shipley, has conducted an enormous number of scientific tests, working under widely varied temperature conditions, and has determined the quantity of refrigeration, the pressures of ammonia, the temperatures corresponding, and the horsepower developed in the steam cylinders of the compressors for each set of conditions. These tests they have been liberal enough to publish in their catalog, so that the information is accessible to anyone.

When these data came into my hands I thought it would be interesting to check up the earlier work of Johnson and see whether his type of equation for the conversion factor between theoretical and actual results was correct. The results seem to me of sufficient importance to publish.

For the benefit of those who have not seen the earlier article, above mentioned, it may be well to explain briefly the formula which connects quantity of refrigeration and power requirements, but first it is necessary to point out a curious condition which has grown up in the refrigerating industries.

The earliest refrigerating machines were put in to take the place of refrigeration with natural ice. As a result they were all rated in tons of "ice melting effect," that is, a "ten-ton" machine would do the same amount of refrigeration as the melting of 10 tons of ice directly applied.

The heat absorbed by ice in melting is a perfectly well known and definite quantity, 142 B.t.u. per pound, or 284,000 B.t.u. per ton, and since refrigeration furnished by ice must be applied at the unvarying temperature of melting ice, 32 deg. F., no other factor than quantity of heat to be absorbed need to be considered. It was like pumping water from one lake with a fixed level to another at a higher level. Quantity was the only variable factor.

But with artificial refrigeration all this is changed because the temperature of application of the refrigeration may be anything from 50 deg. F. above zero to 50 deg. F. below zero, and the power required for a given quantity of refrigeration varies greatly according to the temperatures between which it is performed.

To utilize our illustration again it is like pumping from different wells, the water level of some at the surface, that of others, hundreds of feet below it. Height in this case becomes a factor whose variations are as important as those of quantity. But this change, so important not only in thermodynamics, but also in practice, has been frequently overlooked, and until recently it was customary to give the capacity of a refrigerating plant in "tons," with little or no attention to the temperatures involved. This, of course, is precisely the same as giving only the quantity of water pumped in our second illustration without stating the difference of level through which it was raised.

It is hoped that this article will not only serve as a convenient means of enabling the power required for a stated amount of refrigeration to be determined for the given conditions, but that it will make clear to all the direct and vital connection between the power required and the temperatures involved, and will show the direct application of thermodynamics to this subject.

All students of thermodynamics know that the formula $\frac{T_1 - T_2}{T_1}$ is reversible and applies in theory just as much to refrigeration as it does to development of power from heat. T_1 and T_2, in this case, are the temperatures at which the heat is received and discharged from the working substance, exactly as it is in the same formula for a heat engine, but in this case the heat is received at the lower temperature and discharged at

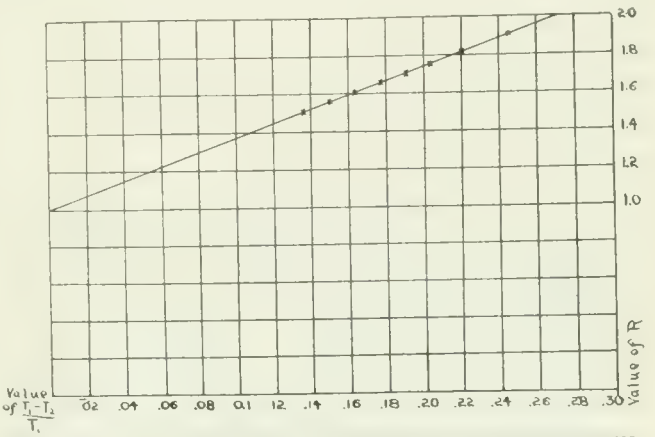

FIG. 1.—R IS RATIO OF I HP OF STEAM CYLINDER OF AMMONIA COMPRESSOR TO THEORETICAL OR DYNAMIC HP FOR DIFFERENT VALUES OF $\frac{T_1 - T_2}{T_1}$ PLOTTED FROM SHIPLEY'S TESTS.

the higher one, therefore, T_1, in this case, is the lower, and T_2 the higher temperature, thus being the opposite to the case of a heat engine.

Any quantity of heat "Q" measured in British thermal units per minute is converted into foot-pounds by multiplying by the mechanical equivalent of heat, 778, and this, in turn, is converted into horsepower by dividing by 33,000. Of this quantity Q the percentage transferred between temperatures $T_1 - T_2$ is given by the formula of thermodynamics $\frac{Q\,(T_1 - T_2)}{T_1}$ and this, in terms of horsepower, becomes $H.P. = \frac{778}{33{,}000}\ Q\ \frac{T_1 - T_2}{T_1}$

$$= .0235\ Q\ \frac{T_1 - T_2}{T_1} \qquad (1)$$

The capacity of refrigerating machines being given in tons per twenty-four hours, this is reduced to thermal units per minute (Q) by multiplying by 284,000, and dividing by 1440, the number of minutes in a day. Thus, 197.+ B.t.u. per minute equals 1 ton of refrigeration per twenty-four hours. Therefore, if we have the temperatures between which a given refrigerating machine works and the number of tons of refrigeration that it performs, we can readily figure the theoretical horsepower required and can then compare this with the actual. The basis on which to make such a comparison is obviously on variations of $\frac{T_1 - T_2}{T_1}$ Accordingly, this quantity has been calculated for a number of the tests whose results are given by

Mr. Shipley, and also the ratio of the actual to the theoretical horsepower required for the same tests. These have been plotted in the diagram, Fig. 1.

Abscissæ are values of $\frac{T_1 - T_2}{T_1}$, ordinates are ratios of actual to theoretical horsepower. It will be observed that a line can be drawn through the points touching, or almost touching, most of them and passing through the point

$$R = 1, \quad \frac{T_1 - T_2}{T_1} = 0,$$

exactly as in the article by Johnson, though these data are more complete than were available to him. The equation of this line is $R = 1 + 3.7 \frac{T_1 - T_2}{T_1}$ (2)

in other words, the excess of the power actually required over

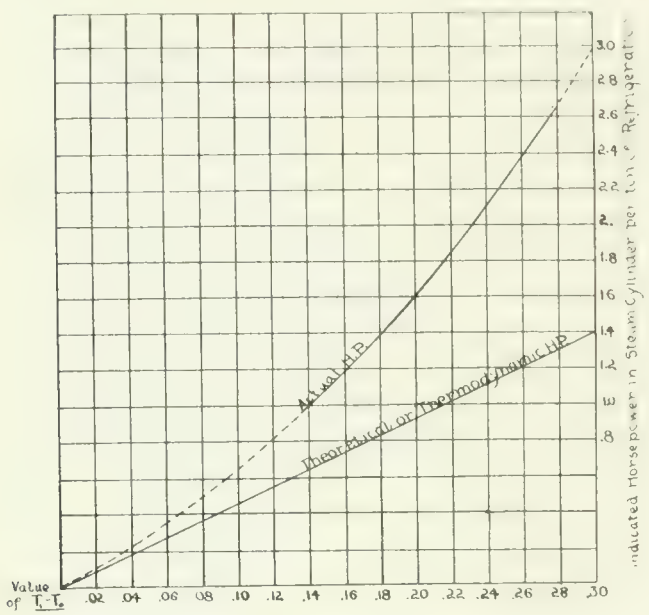

FIG. 2.—SMITH REFRIGERATOR, SHOWING THEORETICAL AND ACTUAL HORSE-POWER REQUIRED PER TON OF REFRIGERATION FOR DIFFERENT VALUES OF $\frac{T_1 - T_2}{T_1}$

that theoretically necessary increases in exact proportion to the increase in $\frac{T_1 - T_2}{T_1}$, or, roughly speaking, it increases in proportion to the temperature difference, which is precisely what we should expect from our knowledge of the conditions.

Comparing this with the formula derived by Johnson from Denton's results, we find that he had $R = 1 + 4.15 \frac{T_1 - T_2}{T_1}$

The difference between 4.15 and 3.7 represents the increase in the efficiency of refrigerating machines since Denton's tests were made.

It is proper to point out also that the results given by the York Manufacturing Company are not the exact power requirements under test conditions in each case, but are about 10 per cent greater so as to represent simply reasonably good operating conditions.

It is believed that this formula will be a tool of real usefulness in the hands of those who will take the trouble to use it. If an engineer has the problem of cooling a given quantity of gas or liquid, or solid, through a given temperature in a given time, he can generally find a reasonably accurate value for the specific heat without much difficulty. This will enable him to figure the number of thermal units per minute to be removed. The temperature to which the given substance must be cooled will, of course, be known as one of the conditions of the problem. The temperature of the cooling water available either from a natural source or from artificial air cooling, controls the temperature of the ammonia condensers T_2 in the formula. The latter temperature will always be about 10 to 15 deg. higher than the former. Similarly the ammonia in the cooling coils must be carried to a temperature about 10 deg. lower than that of the substance to be cooled, if direct cooling is used, or about 20 deg. lower if the ammonia is used to refrigerate brine, and this, in turn, is used to cool the substance under consideration. These, of course, are conditions almost as various and as numerous as the problems to be solved.

But if the temperature of the ammonia condenser and of the ammonia in the cooling coils be known or determined, and the quantity of heat to be removed be known, then the power required for the purpose in good standard practice can be calculated from the formula given above with all needful accuracy for industrial purposes.

For illustration of the above principles; certain reactions will only take place below certain temperatures, or if the temperature gets too high the consequence may be disastrous, as in the case of the manufacture of nitroglycerine. How much power is required to keep the temperature below the critical point?

In such a case the amount of heat evolved per unit weight of material is accurately known or can be accurately determined, and, of course, the weight of material is given. The temperature below which the reaction must be carried on has been found by experience.

Let us assume, in the case of nitroglycerine, that the latter is 50 deg. F., and let us assume that the quantity of nitroglycerine to be manufactured is such that the heat to be removed below this temperature is 10,000 thermal units per minute. Let us assume that it is necessary to use brine in the circulating pipes because the acid used in nitrating would attack iron or steel pipes, which are virtually the only ones that can be used for carrying ammonia. In order to force the heat through the walls of the pipes, let us assume that we must have a 12-deg. interval of temperature for each set of pipes; that is, the brine must be 12 deg. lower than the nitrating tank, and the ammonia 12 deg. lower than the brine. The temperature of the ammonia then becomes 26 deg. F. Let us assume that cooling water is available at the warmest period of the year at 72 deg., and that the corresponding temperature in the ammonia condensers is 85 deg.

It may be well to state here that I am not familiar with the details of the manufacture of nitroglycerine, and the above assumptions are not supposed to be based on actual conditions; they are merely used for purposes of illustration.

For this case T_1 becomes $26 + 460 = 486$, and T_2 becomes $85 + 460 = 545$. $\frac{T_2 - T_2}{T_1}$ becomes .121, for which the value of R from the formula or chart, is nearly 1.45.

The theoretical horsepower required, based on formula 1, in which Q becomes 10,000 and $\frac{T_1 - T_2}{T_1}$ has the value stated, is 28.6. Multiply this by 1.45, we obtain as the actual horsepower required in the engine cylinders, 41.4. This reduces the problem to terms with which engineers are perfectly familiar.

When this article had been completed to this point, it was realized that a still further simplification of this matter was possible, because both the theoretical horsepower required and the ratio R, by which it must be multiplied to give the actual horsepower, depend solely on $\frac{T_1 - T_2}{T_1}$. If, for convenience, we call this latter quanty Z, we have from (1) denoting by hp, the theoretical horsepower,

$$hp = .0235\ Q\ Z,$$

and from (2)

$$R = 1 + 3.7\ Z.$$

Denoting by H. P. the actual horsepower we have

$$H.\ P. = R \times hp = .0235\ Q\ Z\ (1 + 3.7Z).$$

This obviously gives: $H.\ P. = .0235\ Q\ (Z + 3.7\ Z^2)$.

It is obvious from this formula that when the quantity of refrigeration Q and the temperatures are known, the horsepower required can be determined very readily by calculation.

But it can be still more easily obtained from a chart, plotted according to this formula, which is given herewith. The straight line marked "theoretical, or thermodynamic horsepower," gives the horsepower per ton of refrigeration per twenty-four hours required according to thermodynamics. The parabola tangent to this line at the origin and rising rapidly above it, gives the actual horsepower required per ton of refrigeration in any given case, according to the results of Mr. Shipley's tests and to the formula herewith.

Taking the value of $\frac{T_1 - T_2}{T_1}$ equal .121, in the case given above, we find the horsepower per ton from the chart to be .82. The quantity of refrigeration required in tons is the B.t.u. per minute (10,000) divided by 197, or 51. This multiplied by 0.82 gives us 41.4, exactly as before, without the use of any formula whatever.

The portion of the actual horsepower curve, represented by the solid line on the diagram, is that based on actual tests. The dotted portions at the ends are plotted from the formula, assuming it to be correct for temperature ranges higher and lower than those given.

From what has been said above, it will be seen that this is probably more than the reduction of empirical data to a graphic form, and that not only formula (1) but probably also formula (2) represents with close approximation a natural law, since it implies that the losses in a refrigerating process are closely proportional to the temperature interval involved, which is in line with our general knowledge of such matters.

It seems not amiss to point out that this actual horsepower curve emphasizes a law which refrigerating engineers understand thoroughly, but which has not always been realized by others, and that is that the power required for performing a given amount of refrigeration increases enormously with the temperature-interval involved, and for that reason all refrigeration should be done at as high a temperature, be as direct, and involve as few transfers of heat from one medium to another, as the conditions of the given case will permit.

Adobe as a Building Material.—It is possible that in some places in the southwestern part of the United States, and in Mexico, where suitable building material is scarce, adobe may be used for the construction of small mine buildings. The mixture can be prepared by collecting the surface layer of prairie soil where the grass is as thick as possible, adding a suitable amount of water, and then mixing by causing horses to tramp through the mass. Some hand-mixing with fork or shovel may be necessary to insure breaking up lumps. When the adobe has the proper consistency it can be thrown into the wall between upright timbers spaced according to the dimensions of the building. After a layer 12 in. thick has been deposited, and has become hard but not dry, it is trimmed inside and out by laying a board on top of it as a guide, and cutting the adobe with a heavy knife, such as a hay-knife. The width of the board will be the thickness of the wall. Care should be taken to have the successive layers of adobe well cemented to each other to avoid flaws in the wall. Frames for doors and windows can be placed as the building progresses. Plates can be anchored on top of the walls and the roof frame attached to them. Adobe buildings are not likely to settle after they are dry, and they are comfortable.

Platinum was produced by only two of the United States in 1911, California and Oregon. The former produced 511 ounces and the latter 117 ounces. The value of the product was $18,138. Importations of platinum during the same period amounted to 27,500 ounces, nearly four times the domestic production. The world's production of this metal in 1911 was 314,323 troy ounces.

Alumina, Hydrochloric Acid, Caustic Alkalis and a White Hydraulic Cement by a New Process from Salt, Clay and Lime.*

By Alfred H. Cowles.

Since 1862, or earlier, the proposal has been in the literature to produce hydrochloric acid and potassic or sodium compounds from salt and clay by passing steam over the mixture at a high temperature. These proposals have all been condemned as impracticable by Thorpe's Dictionary, Lunge and other high authorities. (Lunge, vol. 2, p. 429, 1895 edition. Thorpe's Dictionary, vol. 3, p. 454.)

It was not until 1902 that a method was patented by Adolf Kayser to effectively and economically separate the silica from an alkali-silico-aluminate formed as one product in the above process. (U. S. patent to Adolf Kayser, dated September 5, 1901; issued September 9, 1902.)

From another cause, the attempts to render this process a success when carried out on a commercial scale, resulted in failure. Namely, if moist clay and salt alone be mixed together, moulded in the form of perforated briquets, and after drying, be heated to a good red heat, but not high enough to melt the final product; and vapor of water be passed through the mass, a chemical action begins on all surfaces of each heated briquet. The vapor of water gives oxygen to the sodium of the salt, and hydrogen to the chlorine, thus hydrochloric acid passes off as a vapor, while sodium monoxide combines with the silica and alumina of the clay, forming sodic-silico-aluminate. This action

FIG. 1.—PARTIAL INSIDE VIEW OF SEWAREN PLANT.

slowly passes inward from the surfaces of all heated briquets. The conversion of the material from the outer surfaces inwards is slow. Kayser, in the nineties, found that it took 72 hours for the change to penetrate through a briquet wall, from its two sides, that was scarcely more than ½ an inch in thickness, and this in a furnace capable of containing many tons of such material.[1]

The result of this slowness of action involved a too long heating of the briquets, necessitating an abnormally large volume of nitrogen and fuel gases passing through the furnace to effect the result. The quantity of these inert gases was so great, that the hydrochloric acid fumes evolved were not capable of efficient and practical condensation.

Adolf Kayser died in Lockport, N. Y., on November 26, 1910, of heart failure at the age of seventy-three. He came originally

*An abstract of a paper presented before the Section on Inorganic Chemistry of the Eighth International Congress of Applied Chemistry on September 12, 1912.

[1]Mr. Cowles exhibited one of Kayser's briquets. It has a crystalline structure. Though shrunken somewhat, it has retained its moulded form.

from the Hartz mountains, a simple yet energetic man in his habits, one loved by all and highly admired by those who could understand his clear philosophical reasoning. He, like Leblanc, failed to realize his thirty years dream of success. Unlike Leblanc, he was happy in his latter years in following his passion for original chemical research. He discovered a soluble sodic-silico-aluminate of high detergent value, now finding its way into commercial channels as a substitute for soap.

While he was thus employed as a chemist with the Electric Smelting & Aluminum Company, of which the author is president, I suggested that we make up some salt and clay briquets adding charcoal or sawdust to the mixture to render them porous during heating, and test them out in a comparable manner with similar briquets of clay and salt alone, such as he had formerly used in his attempts to render the process mentioned commercial. He did not think this mixture would work, as he was positive that it would destroy the oxidizing atmosphere needed in the operation to prevent the formation of volatile aluminium chloride (Al_2Cl_6. I believe that an oxidizing atmosphere was only necessary around the briquets, and that it would gradually penetrate the mass of each briquet, and that a reducing atmosphere at interior portions of such briquet could not interfere with the desired reaction, as any aluminium chloride formed would of necessity change to oxide before leaving the briquet. Without mentioning this to Dr. Kayser I insisted upon the trial being made. It was made. The bricks containing charcoal were converted into sodic-silico-aluminate in one-ninth of the time that was required with like briquets containing no charcoal. Seventeen deg. Beaume acid was condensed from a small apparatus in the face of imperfect control.

This experiment opened up an entirely new vista of success to the process. It meant that the volume of fuel gases and nitrogen necessary to pass through a charged furnace would become so reduced as to permit of efficient commercial condensation of the hydrochloric acid evolved. It meant a great saving of fuel and far greater capacity of output with the same cost of plant. The doctor and myself became equally enthusiastic. Our company acquired his patent for opening or rendering soluble the alumina in the form of sodic-aluminate from the sodic-silico-aluminate briquets produced, and after two years or more of added experimental work in the laboratory a large plant has been erected at Sewaren, N. J.

The process as a whole is easily understood. The clay, carbonaceous matter, and salt are made into perforated briquets and after being dried in a drying kiln they are passed on flat cars through a long furnace of the tunnel type which brings the briquets to a temperature of about 1035 deg. C.

Knowing the composition of the clay, and the percentage of salt in the mixture, steam is blown into the discharge end of the furnace over a train of cars covered with firebrick, with their iron parts sealed off, while through a vestibule at the other end of the furnace loaded cars are gradually pushed forward by a hydraulic pusher whose speed is under control. The weight and composition of the material on the cars thus fed into the furnace is known, and the correct proportional weight of exhaust steam is passed into the furnace from the opposite end. From the charging end the gases at a temperature too high to attack iron are sucked by a large blower and forced through a large hydrochloric acid condensing system. The temperature of the furnace is controlled by oil heat and measured by pyrometers. Most of the heat required is furnished by the carbonaceous material mixed with the clay and salt of the briquets. The reaction that takes place will vary according to the composition and mixture of the aluminous material and the salt, but typically, the final reaction is as follows:

$$Al_2O_3 2SiO_2 + 4NaCl + 2H_2O + xH_2O + xC = xO$$
$$(Na_2O)_2(SiO_2)_2Al_2O_3 + 4HCl + xH_2O + xCO.$$

The surplus vapor of water and the hydrochloric acid gas are carried into the condensing apparatus and are condensed. The briquets maintain their original form as the cars bearing them are gradually pushed out of the discharge end of the furnace, having been cooled by the rapidly rising rush of measured

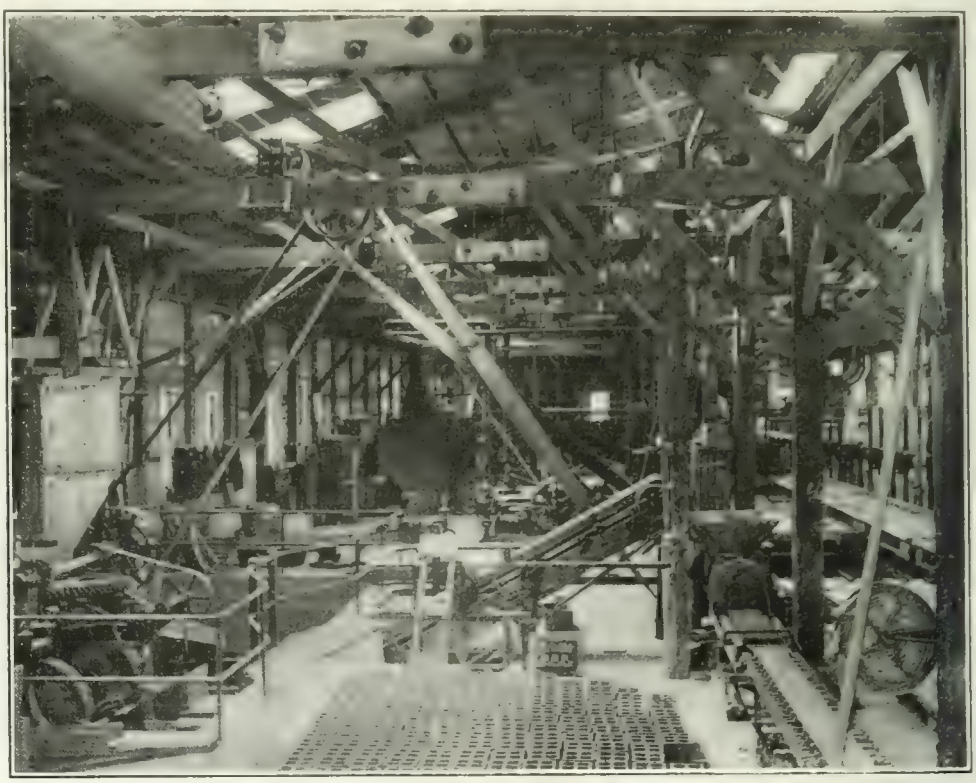

FIG. 2.—BRIQUETTING MACHINERY

steam and a limited quantity of air while nearing the exit.

The sodic-silico-aluminate briquets formed have been made containing as high as 33 per cent of sodic oxide. The above reaction would give 35.8 per cent Na_2O. There is no appreciable loss of salt. While pure clays are preferred, all small amounts of iron pass off as iron chloride with the hydrochloric acid and are condensed with the first hydrochloric acid in the first condensers of a multiple series system. The acid produced is remarkably pure, free from arsenic, and but traces of sulphuric acid can come from iron pyrite if the same be in the clay. When briquets are made containing 32 per cent of sodic-oxide the output of 30 per cent hydrochloric acid should be about 1½ tons of acid to 1 ton of salt and clay mixture charged into the furnace.

The next step in this process is to open the sodic-silico-aluminate, which is acid, to secure from it the sodic aluminate which it contains. This is accomplished by heating a mixture of ground acid salt with just sufficient lime to combine with the silica in it and form di-calcium silicate.

$$(Na_2O)_2(SiO_2)_2Al_2O_3 + 4CaO =$$
$$2(CaO)_2SiO_2 + (Na_2O)_2 + Al_2O_3$$

Limestone, calcite or marl in their chemical equivalent to lime may be used instead of anhydrous lime.

In the reaction just given, any amount over two molecular weights of calcic oxide to each molecular weight of silica, leads to formation of insoluble calcic aluminate, while less than two molecular weights is not sufficient and leaves undecomposed sodic-silico-aluminate. In each of these cases, marked loss in the recovery of alumina may occur. The mixture of lime and the acid salt is heated in a rotary cement furnace, or in a furnace of the tunnel type as above described, just to its clinkering temperature. After its discharge from the furnace, it is broken into fragments and these are in an excellent physical condition for effective leaching. Very nearly all of the sodic aluminate may be leached from this clinker, while there is left behind a white mass of dicalcium silicate containing some sodic aluminate.

Having secured the sodic aluminate in solution, the method of procuring the alumina and caustic soda therefrom is that already in universal use.

The residue of dicalcium silicate when heated in a cement furnace with one molecular weight more of lime, gives a clinker that conforms in composition to Newbery's formula for the best and strongest hydraulic cement, but it has the advantage that all of the iron oxide has already been removed from the silica that goes into its composition, thus rendering it easy to secure a white cement by the use of limestone free from iron.

Such cement sells at about four times the market price of ordinary cement.

This process opens the way to secure the alumina cheaply, or as a by-product in conjunction with these other products, of great consumption in the industrial arts. There is required, 1.9 lb. of alumina, to produce 1 lb. of aluminium by the present method of manufacture. This costs 6½ cents and is the heaviest item of cost in producing this metal. By the general introduction of this process, we may hope to see the cost of production of the metal aluminium reduced four or five cents a pound.

This process also furnishes a key to unlock the stores of potash from the world's mountainous masses of potash feldspar. As one way to do this effectively, the feldspar should be ground and mixed with either chloride of sodium or chloride of potassium and made with some clay and sawdust into the form of briquets, then passed through a furnace under conditions similar to those described above. The solid product should then be submitted to Dr. Kayser's lime opening process. The clinker on leaching gives potassic aluminate or a mixture of this with sodic aluminate from which the alumina may be separated, and the potash or potash and soda secured for use in fertilizers. The residue from leaching can then be converted into hydraulic cement.

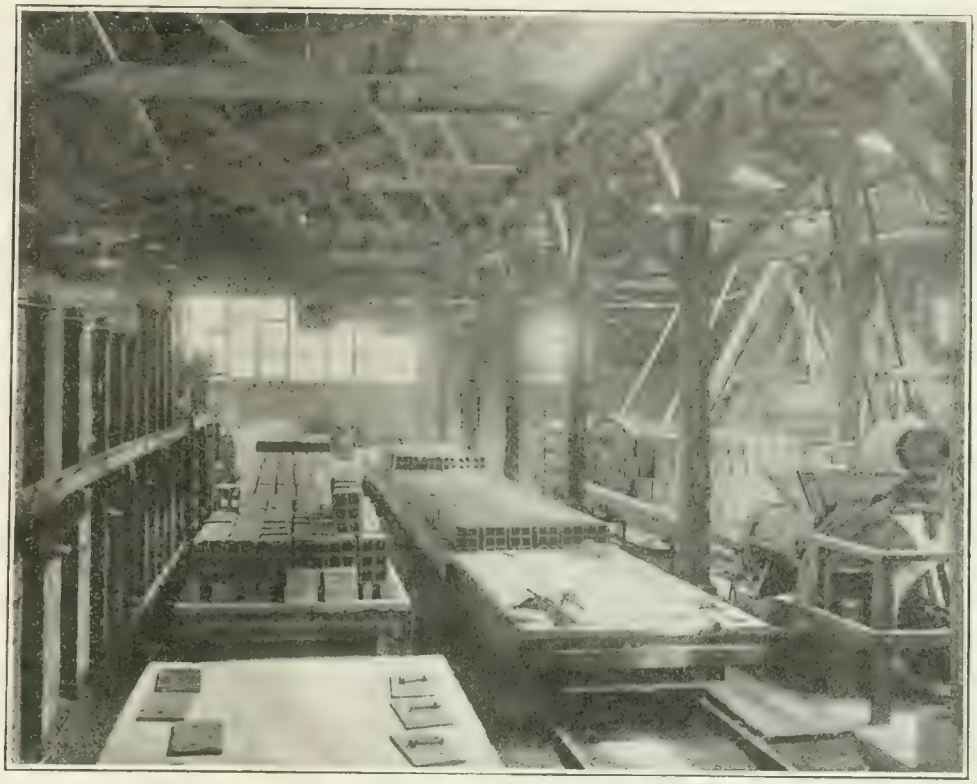

FIG. 3.—CARS WITH BRIQUETS READY TO GO INTO FURNACE.

FIG. 4.—VESTIBULE WHERE CARS ARE ADMITTED TO LONG CHANNEL.

A study of the reactions herein given in connection with the volatilizing temperatures of the various chlorides of the common metals will throw much light upon the geological theories of formation of intrusive mineral veins.

Before closing this paper, I wish to express my pleasure at being able to do homage to Mr. Kayser and make known the splendid work of an able enthusiastic genial chemist, without whose aid the above described process as a whole would never have attained the completeness that it now has, and the great usefulness that future years will confirm.

Discussion.

In reply to a question whether any attempt has been made to catch and utilize the CO, Mr. Cowles replied that this had not yet been done, but may eventually be done as CO is utilized from blast furnaces. To remove small amounts of HCl from it, it should be passed through a proper scrubber.

In reply to a further question as to what use is made of white cement and whether the same has been made, Mr. Cowles said that white cement has high value for use in decorative work. They have, however, only made the dicalcium silicate. Adding one molecular weight of CaO to the same they know that they come within the formula discovered by Arthur Newbery for the strongest hydraulic cement, which formula permits up to several per cent of Al_2O_3 to be present in tri-calcium silicate, and if iron oxide be absent this produces a strong white cement.

Dr. A. S. Cushman asked whether the reactions are theories or have they been worked out on a large scale? Why does not the NaCl distil off? At what temperature does the final reaction take place?

Mr. Cowles in answering the first question said that the reactions have been worked out on a large experimental scale during three years work previous to their starting to erect the plant at Sewaren, N. J. He expected to have converted briquets from a channel furnace, 180 ft. long, at the meeting—the first from the new plant. But the day before an engine cylinder went to pieces that operated their generator, which furnished current to the motors driving the blowers connected with the furnace. This stopped the furnace with the bricks just approaching the hottest zone in the furnace. Acid was condensing in their condensing system at this time.

The NaCl is decomposed by superheated vapor of water before it has a chance to distil off. Some will vaporize in the hot zone of the furnace and be carried over the loaded cars. For about 90 ft. the hollow briquets act as a scrubber and carry the sublimed salt back toward the hottest zone of the furnace. Using too high a percentage of NaCl in the briquets might clog the furnace, for it would be capable of forming more Na_2O than the clay would be able to absorb. The limit above that required to place 33 per cent of Na_2O in the product will probably be higher with their large furnace than with the small furnaces that they formerly employed.

In answer to the third question, Mr. Cowles said that the reaction begins at a lower than the vaporizing temperature of salt. Two days before the meeting the hottest part of their large furnace was 1450 deg. F. and acid fumes so strong were passing through the condensing pipes that it was with difficulty that U-shaped pipes were connected between one set of upright acid ware pipes to permit the fumes to pass through other sets, and weak acid was drawn from the condensers. After the vaporizing temperature of NaCl about 1700 deg. F is passed, the reaction goes on very rapidly. The higher the Al_2O_3 in the clay the higher can the temperature be carried without melting the briquets.

Mr. L. P. Brown asked what purity of clay is required? Mr. Cowles replied that the purer the clay the better, as the presence of iron-oxide leads to a larger amount of iron chloride and loss of pure acid. If the iron chloride were used for leaching ores or otherwise, then its presence would not be so detrimental. The Moraine clays contain an undesirable amount of iron oxide and are most too low in alumina for obtaining the best results.

Mr. H. W. Charlton asked whether the process would work in an electric furnace with steam passed through a hole in the electrode?

Mr. Cowles replied that it would not work economically. Neither clay, silica or alumina will be fluxed by boiling salt. Vapor of HCl would come out of such a furnace and could be detected but it would be associated with sublimed salt and solid matter without complete transformation of the latter.

Resistance of Refractory Ware Against Abrupt Changes of Temperature.

By Paul Wiegand

In the manufacture of refractory ware, besides the usual criterions such as refractoriness, density and chemical constitution, account must also be taken of the capacity of resisting abrupt changes of temperature.

In order to establish how far the size of both grog and binding clay have any influence upon the resistance against abrupt changes of temperature, special tests have been made by means of fire bricks 25 cm. by 12 cm. by 6 cm.

The investigations, which were carried out at relatively low temperatures (900° = 1000° C.), showed that by increasing the size of the grog particles and decreasing the percentage of binding clay in the mixture, the resisting capacity of fire bricks against abrupt temperature changes was essentially increased. No standard units for the measurement of a definite resistance against temperature changes have until now been proposed and no reference concerning the selection of those units can be found in literature bearing on the subject. It would, therefore, be advisable to establish standard rules from competent authority which would be accepted as a generally recognized standard for testing the capacity of resisting changes of temperature.

The suggestion for this inquiry was found in the fact that even high grade refractories often show a failure, either from being too porous or too dense; and that in the latter case they show more or less deep cracks. In both cases there is an uneven surface formed which offers less resistance to chemical agents and which shortens the life of the brick considerably.

Composition of the brick used during the tests	Size of grog	No. 1 Test. Five bricks were tested in a muffle at a temperature of 950° C. for 20 minutes, then cooled down in the open air.	No. 2 Test. These bricks were examined and tested after the first test were heated in a muffle at 950° C. for 20 minutes, then a jet of cold air was blown over them for three minutes and were allowed to cool down in the open air.
Five parts of binding clay to five parts of grog.	0.75 mm to 6 mm	No cracks.	Small cracks.
	0.75 mm to 4 mm	" "	" "
	0.75 mm to 1 mm	Numerous small cracks.	" "
	0.00 mm to 0.75 mm	Parts of brick blown off.	" "
Three parts of binding clay to seven parts of grog.	0.75 mm to 6 mm	No cracks.	No cracks.
	0.75 mm to 4 mm	" "	Small cracks.
	0.75 mm to 1 mm	" "	Numerous small cracks.
	0.00 mm to 0.75 mm	Small cracks.	" "

Translated from *Ton Industrie Zeitung* (Berlin), by E. C. Buck, St. Louis, Mo.

The temperatures used in carrying out the above described tests are far remote from the excessive temperature obtained in industrial and metallurgical furnaces. It was thought advisable to publish the above communication and results of the tests to our readers in the hope that the question entered upon by the author might be taken up for further elucidation.

Mining and Milling Machinery in New Zealand.—According to U. S. Vice-Consul General Henry D. Baker, the United States supplies New Zealand with only about one-fourth of its imports of mining machinery, and he considers that there is an opportunity for extending this class of business there. Machinery from British countries is admitted duty-free, but there is a tariff of 10 per cent on machinery from countries outside the British empire. A study of local conditions is urged as essential in seeking this trade, and local representatives are deemed advisable. The treatment of slime in the cyanide process offers an opportunity for the use of American machinery.

The Electric Steel Furnace in Foundry Practice.

By Paul Girod.

More and more the electric steel furnace is extending its influence in foundry practice as a useful aid to the open hearth and as a sharp competitor to the crucible or small converter.

This evolution is due to the possibility and ease of turning out a high-quality steel at a cost much lower than with the crucible process, and to the simultaneous advantage of producing a quality of steel superior to converter and open-hearth steel. Foundrymen are, therefore, becoming aware of the great possibilities of the electric furnace as a simple apparatus for making best-quality steel castings.

The electric steel furnace is especially well suited for castings since it offers the possibility of holding finished steel in the furnace as in a mixer and to tap it at intervals as desired into small ladles. Different taps can be made at different temperatures, lower temperatures being used for larger molds and higher ones for small castings. The steel can be heated to any desired temperature and castings can be made very thin-walled and of a very small size. Pieces from ½ lb. and upward with sections of 5 to 7 mm. thickness can be cast without any difficulty.

With the electric furnace one is sure to have for castings an absolutely dense steel without blowholes and pipes. Figs. 1, 2, and 3 relate to some small castings of extra soft steel.

The average results of analytical and mechanical tests of detached pieces of the castings were as follows:

C	Si	Mn	S	P	E	R	A	Charpy
0.08	0.05	0.37	0.022	0.017	24	36.5	32	24 Kilograms
0.10	0.32	0.43	0.022	0.017	25	40.7	28	23 Per square mm
0.24	0.21	0.45	0.024	0.020	28	44.0	27	32 Formula for elongation
0.31	0.22	0.48	0.018	0.018	28.7	48.1	25	20
0.36	0.31	0.44	0.024	0.009	30.7	49.0	24	19.5 L. $\sqrt{66.67 S}$.

A cold-bending test is shown in Fig. 4.

Recently a very important improvement has been realized by introducing into electric steel practice for castings the use of special titanium alloys such as manufactured by the Société Anonyme Electrométallurgique Procédés Paul Girod of Ugine (Savoie), France, of approximately the following compositions:

I. Si : 56 per cent Ti : 36 per cent
II. Si : 21 per cent Ti : 28 per cent
III. Si : 10 per cent Ti : 10 per cent

Even very small additions of these alloys render the steel perfectly quiet, and insure the castings to become very dense and free from any blowholes. The number of lost heats can be very much diminished.

The microphotographs, Figs. 5 and 6 represent electric steel made with the aid of titanium alloys, and show the perfect density of the steel and the absence of any traces of oxides and blowholes. These microphotographs are magnified 220 diameters.

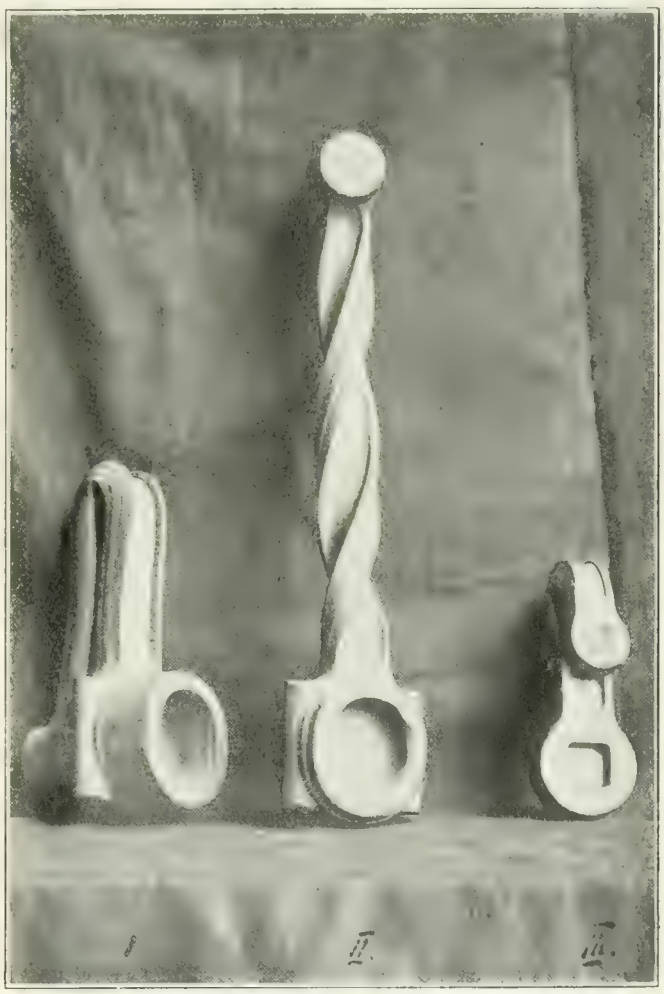
The construction of the Girod electric furnace is very simple. It is a hearth furnace formed by a rectangular or circular iron shell, and lined with refractory material. The furnace is fitted with a sliding door, through which the furnace is being charged and slag is being removed; opposite the door is the tap hole. The arched roof is made of silica bricks with metal framework.

The current is supplied by carbon electrodes hanging vertically into the furnace, their lower ends being near the slag level as in other furnaces.

In the bottom of the furnace and as far away as possible from the upper carbon electrodes, six or more steel electrodes pass through the refractory bottom and are also in direct connection with the furnace shell and the low-tension side of the power plant. The current is thus forced to pass through the charge. By this means the whole mass is uniformly heated, the bath not being simply licked on the surface by the arc. Moreover, the current passing through the bath produces an electromagnetic field which gives the bath a rotary movement, accelerating the chemical reaction. The steel electrodes are water-cooled, and their lives are practically unlimited.

The steel frame is placed on rollers so that it can be tilted forward for the tapping or backward for the removing of the slag, which is done through the charging door. Since there is only one door an easy access to the furnace is assured and the entrance of too much air is prevented. The furnace is tilted by means of an electric motor or hydraulic plunger.

The furnace can be operated by any system of current, continuous or single-phase or three-phase current being suitable. The usual tension is 65 volts for small furnaces, and 70 volts for big ones. The frequency may be up to 50 periods, but on



FIGS. 1 TO 3.—SMALL CASTINGS OF EXTRA SOFT ELECTRIC STEEL

account of the effects of self-induction, it is much better to have a lower frequency, the electric efficiency being higher. On account of the low voltage of the furnace the workmen are not subject to any danger.

The use of single-phase alternating current is especially suitable for furnaces of small capacity with only one carbon electrode. Its use, however, entails in a three-phase distribution system in general the necessity of installing rotary converters or motor-generators with about 14 per cent transformation losses.

With a three-phase furnace merely the installation of step-down transformers is required with energy losses of only 3 or 4 per cent. For this reason, we recommend for operation by three-phase currents the use of furnaces with more than one electrode. Our special patented method of connections allows to feed our furnaces with three-phase currents with equal load on all three phases. With this kind of connections the current

passes through the whole bath, so that the great advantage of the Girod furnace, viz., the uniform heating of the whole bath is equally well attained in three-phase furnaces as in single-phase ones.

Figs. 7 and 8 show the general arrangement of a single-phase furnace and of a three-phase furnace respectively.

STEEL REFINING IN THE GIROD ELECTRIC FURNACE.

The Girod furnace is suitable for the melting and refining of ordinary scrap or steel waste of every composition. The

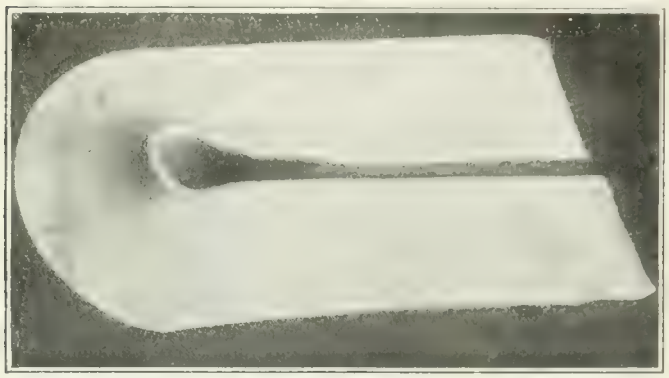


FIG. 4.—COLD BENDING TEST.

addition of pig iron to the charge is not necessary, and its use in small proportions offers advantages only in the case of highly oxidized raw material.

Metallurgical Reactions.—The operations can be divided into two periods:

1.—Oxidation period.

2.—Deoxidation period.

First Period.—An oxidizing slag is formed by adding to the charge some lime and iron ore. The proportion of these additions varies according to the chemical purity of the charge, and is determined in such a way that when the melting is completed the bath contains less than 0.1 per cent C. Mn and Si. In this period of refining the oxidation takes place vigorously and the original low temperature of the bath favors the elimination of the phosphorus. Practically all phosphorus is removed before slagging.

A forging test will easily show whether the metal is in the extra-soft state. In this case as soon as the temperature of the bath has become sufficiently high the slag containing phosphorus and iron oxides is tapped off through the charging door by tilting the furnace slightly backward. The first slag is immediately replaced by some lime which cleans the bath from the last traces of phosphoric slag. One slag is generally sufficient to remove all phosphorus down to traces.

Second Period.—The oxidizing and cleaning slag being removed, a first deoxidation of the bath is effected by adding deoxidizing agents, such as ferro-silicon, ferro-manganese, etc., these alloys being added in such proportion as not to remain in the bath. At that time recarburization takes place if hard steel is to be made.

Then the bath is rapidly covered with a slag consisting of about five-seventh of lime, one-seventh of silica sand, and one-seventh of fluorspar, together with a slight addition of carbon in the form of petroleum coke.

In this second period of deoxidation care must be taken that the furnace be properly closed, the temperature being held sufficiently high so that the iron oxide in the slag is reduced. The destruction of the ferrous oxide in the slag is indispensable for the deoxidation and desulphurization of the bath. It is gradually reduced by deoxidizers, such as ferro-silicon, and the addition of some petroleum coke to assure complete deoxidation, and a slag will be obtained which, in the air, disintegrates into a white powder, the ferrous oxide being reduced down to traces.

In order to push on the complete deoxidation of the bath it is useful to add small quantities of silico-manganese, or ferro-silico-manganese-aluminium, or even silicon-aluminium, these alloys acting very energetically upon the oxides in the bath, forming a very fluid slag which easily rises to the surface.

During the same period, when the slag is completely deoxidized and is very basic, the desulphurization which was incomplete during the first stage of the operation proceeds further, and is rapidly completed at the time of tapping. Desulphurization starts vigorously when the highly basic lime slag becomes white and readily fluid, *i.e.*, after the removal of the metallic oxides. Carburizing materials are eventually added for finishing the metal and the final addition of ferro-silicon, ferro-manganese, etc., is made in order to arrive at the required composition of the steel.

The average analysis of the final white slag is as follows: CaO, 74.85 per cent; SiO_2, 13.20 per cent; FeO, 0.13 per cent; MnO, traces; S, 1.2 per cent; Fe_2O_3, none; Al_2O_3, 1.75 per cent; MgO, 4.22 per cent; P_2O_5, 0.09 per cent.

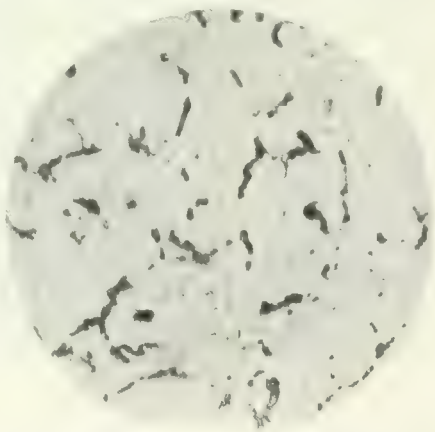
COST OF REFINING.—COLD CHARGES.

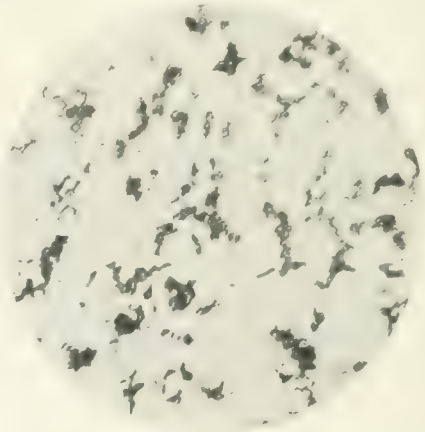
Power Consumption.—The power consumption recorded at the terminals of the furnace and including smelting, refining, and finishing a charge of cold scrap is about

850 kw-hours per ton of metal tapped for a 3-ton furnace.

750 kw-hours per ton of metal tapped for a 10-ton furnace.

Of course, these figures vary with the composition of the charge. According to the quality of the steel and its purity, the figures may be higher or lower than those quoted.





FIGS. 5 AND 6.—MICROPHOTOGRAPHS OF STRUCTURE OF ELECTRIC STEEL WITH TITANIUM TREATMENT.

Consumption of Electrodes. — The consumption of electrodes per ton of steel made is about

8 to 9 kilograms for a 3-ton furnace,

8 to 10 kilograms for a 10-ton furnace.

These figures indicate the consumption of electrodes of good quality, as manufactured in our own electrode factory at Ugine, and may be considerably reduced by the latest improvements introduced in the manufacture of the electrodes which permit them to be completely used up.

Wages.—The furnace needs:

1 smelter, 1 second hand, 1 boy for the 3-ton furnace.

1 smelter, 2 second hands, 1 boy for the 10-ton furnace.

Maintenance and Repairs.—The furnace can be lined with magnesite bricks or better tamped with tarred magnesite or

dolomite. Dolomite-tamped bottoms are giving the best results. The work is done with heated hand tampers or with pneumatic rammers. The life of the lining is about 90 to 100 heats for a furnace of 10 tons and about 120 heats for the 3-ton furnace. At the end of that time the side walls and the hearth will need repairing. All the burned or oxidized parts of the walls are scraped. The bottom is broken down about 10 to 15 cm. and is retamped with new layer of dolomite, taking care to leave intact the passage of the tops of the bottom electrodes. This repair of the upper part of the bottom is the only one required, the damage of the walls at the slag line being repaired between charges with dolomite.

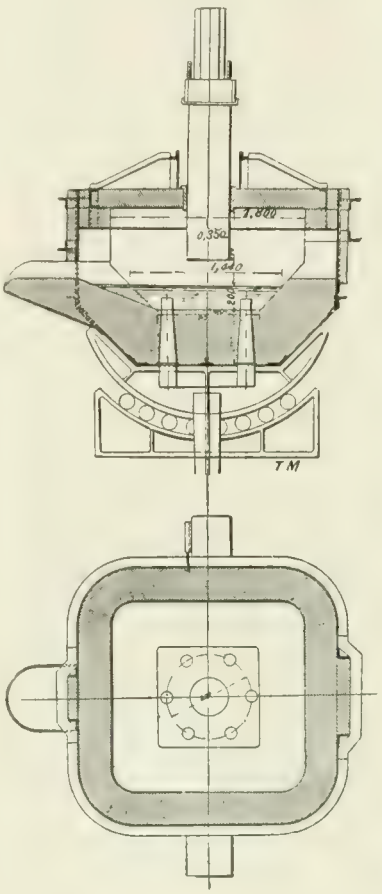


FIG. 7.—SINGLE-PHASE GIROD FURNACE.

The roof of the furnace is made of silica brick and stands on an average fifty heats for the 10-ton furnace and seventy heats for the 3-ton furnace.

Additions.—Lime, ore, silica, sand, fluorspar, petroleum coke, to make the slag, and ferro alloys for deoxidation and finishing.

The total of this expense varies considerably with the purity of the raw material used and the quality of steel.

Heating Losses.—The output is about 90 to 96 per cent of the charge; it depends much on the degree of the oxidation of the scrap.

COST OF REFINING—LIQUID CHARGES.

With liquid charges, on the other hand, where the working period for a heat is only 2 to 2½ hours, the cost of electric steel refining is considerably reduced and allows a reduction of more than 25 per cent on the cost price according to the local conditions.

On the lines of these conditions and indications we arrive at the following *estimate for the cost price per ton of steel tapped with our system:*

COLD CHARGES.

Raw Material:

	3-ton.	10-ton furnace.
Scrap, 1100 kgs. at frs. 75 per 1000 kgs.	82.50	82.50
Slag	2.30	2.30
Deoxidizing additions and recarburization	3.50—88.30	3.50—88.30
Producing Cost:		
Electric power, 850 and 750 kw-hours at 2 centimes	17.00	15.00
Electrodes at frs. 320.00 per ton	3.00	3.50
Wages	3.00	1.50
Maintaining and repairs	12.00—35.00	8.00—28.00
Total cost per ton, francs	123.30	116.30
or	$24.66	$23.26

MOLTEN CHARGES.

Raw Material:

	3-ton.	10-ton furnace.
Liquid steel 4 per cent loss in heating, 1040 kgs. at frs. 80 per ton	83.20	83.20
Slags	2.00	2.00
Deoxidizing additions	3.50—88.70	3.50—88.70
Cost of Producing:		
Electric power, 275 and 200 kw-hours at 2 centimes	5.50	4.00

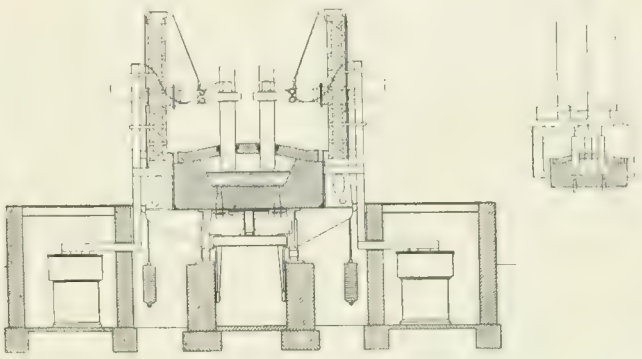

FIG. 8.—THREE-PHASE GIROD FURNACE.

Electrodes 3 to 4 kgs. at frs. 320 per ton	1.25	1.25
Wages, 8 heats in 24 hours	1.00	1.00
Maintenance and repairs of the furnace	4.00—11.75	2.50—8.75
Total cost per ton of steel, francs	100.45	97.45
or	$20.09	$19.49

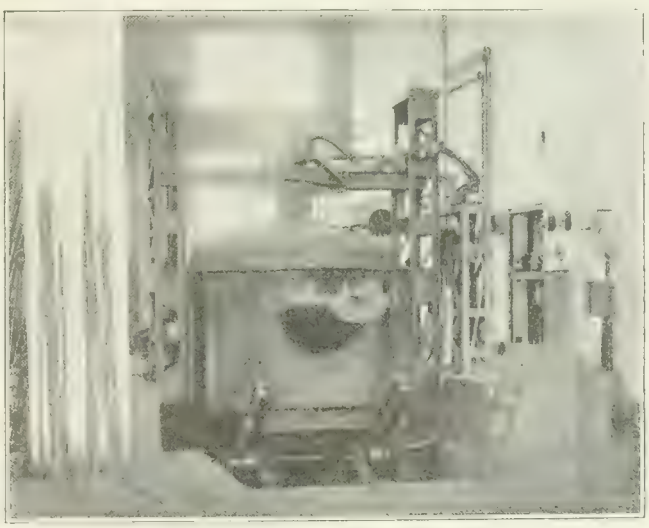

FIG. 9.—TWO-TON GIROD FURNACE FOR STEEL AND MALLEABLE CASTINGS AT STOTTZ WORKS, STUTTGART, GERMANY.

The estimate does not include the expenses for ingot molds, superintendence, laboratory, amortization, and general charges, which vary so considerably as not to allow a fair average estimate.

Ugine, Savoie, France.

Alumite, which promises to become an important source of potash in the United States, is found in the San Cristobal quadrangle in Colorado. Analyses of the mineral indicate that it exists in probable commercial quantities.

Coarse Crystallization Produced by Annealing Low-Carbon Steel.

By R. H. Sherry.

The production of large crystalline grains during the annealing of low-carbon steel is a phenomenon often observed in plate sheets and other similar material which has been annealed at temperatures between 650 and 690 deg. C. One of the earliest references to the subject is by Stead in his "The Crystalline Structure of Iron and Steel," published in the *Journal of the Iron and Steel Institute* for 1898, Vol. 1. In this article he makes the following mention of this phenomenon:

"In practically carbonless pure iron and steels of fine grain produced by forging or certain heat treatment, the grains increase in size slowly at 500 deg. C. and more rapidly at between 600 and 750 deg. C., and it is possible by heating at about 700 deg. C. for a few hours to develop granular masses of exceeding coarseness. . . . . As soon as the temperature rises to above 900 deg. C. the granules again become small, and heating to 1200 does not apparently produce any difference in their dimensions."

In Vol. 2 of the same journal for 1898, Stead, in his paper "Brittleness Produced in Soft Steel by Annealing," makes mention of the same phenomenon in soft steel sheets containing 0.05 to 0.12 per cent carbon annealed for forty-eight hours. Laboratory attempts to produce this structure at will were not invariably successful.

As a further advance in the study of this phenomenon came the work of Charpy (*Comptes Rendus,* Vol. 151) showing that this coarsely granular structure could be produced in steel low in carbon and phosphorus by performing cold mechanical work on the steel and subsequently annealing at 700 deg. C. The specimens were worked by means of a screw plate and examination of them after annealing showed that the grains had increased to about ten times their original size. He also found that there was no limit to the size of the grains produced by annealing at the proper temperature, which varied with the nature of the steel, and that by annealing long enough the entire specimen could be converted into a single grain.

The object of this paper is to give a brief outline of the results of some experiments conducted with the idea of throwing some light on this phenomenon of the coarse crystallization of annealed low-carbon steel. In this work the temperature ranges noted by Stead were partially confirmed, and also the effect of cold mechanical work found by Charpy, but it was not possible to produce all the phenomena noted by them. This is especially true in regard to the increase in grain size due to long annealing. Nearly all the test pieces used in this investigation were annealed for periods of from one to forty-eight hours and no variation in grain size was found due to the increase in the time of annealing. It was found, however, that it was necessary to anneal for at least forty-five minutes to produce the grain growth. Nor was it possible to obtain the very large grain mentioned by them. The largest grain size obtained in this work was 0.80 mm. linear dimension, an increase to about forty times the original size. The photo-micrograph accompanying, taken with 100 diameters enlargement, shows the size of the grain in this specimen. Under the conditions by which this was produced, a matter which will be mentioned later, it was not possible to remove all the fine grain structure, and a number of grains which remained unacted upon will be seen in the photograph and serve by comparison to give some idea of the increase in grain size.

The first experiments were undertaken with steel which was known to crystallize when annealed at about 700 deg. C. The samples used were 0.3 in. in diameter. Of the previous history of this steel nothing was known except that it had received cold mechanical work. The analysis was:

Carbon.	Manganese.	Sulphur.	Phosphorus.	Silicon.
0.08	0.34	0.032	0.010	0.020

The grain size before annealing was 0.02 mm.; after annealing this increased to 0.52 mm. With this steel the temperature range within which crystallization would occur was found to lie between about 690 and 775 deg. C. Heating to 800 would remove any crystallization and would prevent its occurrence if the steel was subsequently annealed at 700 deg. C. On annealing below 690 there was no grain growth.

To study the effect of mechanical work a series of forging tests were made with this steel. It was found that on heating to various temperatures from 800 to about 1200 deg. C., to remove the tendency to crystallize, and then hammering the piece until the temperature had fallen to about 700 deg., no crystallization could be produced by subsequent annealing at 700 deg. If, however, the temperature was allowed to fall well below 700 before forging was stopped it was found that an increase in the grain size would occur if the sample was given the usual annealing at 700 deg. This grain growth, however, was confined to an area about ⅛ in. in from the circumference. In no case was the increase as large as that obtained with the steel in its original condition, but varied from 0.10 to 0.27 mm. On hammering cold a sample of the steel and subsequently annealing it was again found that the grain size did not increase as much as in the unhammered steel. Repetition of this experiment gave grain sizes of from 0.12 to 0.30 mm.

Further forging tests were made on samples of hot rolled steel of various sizes with practically the same result. Forging below about 700 deg. and subsequent annealing would cause the steel to crystallize around the circumference. Preliminary test showed that none of the hot rolled test pieces would crystallize on annealing. As found in the experiments with the first steel there was a considerable variation in the grain size of the forged and annealed test pieces. These results are purely qualitative and gave no key to the cause of this variation in grain size, and in order to obtain more quantitative results it was decided to try the effect of cold drawing and cold rolling where the amount of work could be determined in terms of the reduction of area.

In order to try the effect of cold drawing a series of hot rolled rods varying in size from ¼ in. to ½ in. in diameter were drawn with varying reductions of area and then annealed for one hour at 700 deg. C. The results of these experiments showed that in order to produce this increase in the grain size it was necessary that the amount of mechanical work be quite light. In general the lighter the work performed the larger the grain size. There was a limit to this, however, and no result was obtained with extremely light drafts. In general it was necessary to have at least 7 per cent reduction of area in order to obtain any increase in the grain size, though often with lighter drafts followed by annealing there would be a slight increase confined to the outer area, similar to that obtained in the forging tests.

Samples of all the drawn test pieces were annealed at various temperatures between 600 and 900 deg. C. The results of this experiment showed that if the reduction had been about 9 per cent or less crystallization would occur only when the steel was annealed between about 690 and 775 deg. C. On the other hand, if the amount of work corresponded to more than 9 per cent reduction, crystallization would occur between 650 and 875 deg. C.

To illustrate the effect of mechanical work four series of tests have been chosen from the experimental results, and are given in the appended table.

Another series of tests was made on cold rolled material, the results being practically the same as obtained with cold drawing. It was not possible, however, to obtain quite as large grains, and some variation was noted in the annealing range, as all the cold rolled specimens showed increase in grain size when annealed between 700 and 875 deg. C. No increase could be obtained by annealing at 650 deg., and heat-

ing to 900 removed crystallization and all tendency to crystallize. Two series are given in the table.

On examination of the results obtained by these experiments it will be seen that a number of variations from the results of Stead and Charpy were found, although the general features of the results of cold mechanical work are the same. The quantitative effect of cold mechanical work in the form of cold drawing and cold rolling have been measured and the connection with the temperature range outlined.

The composition of the steels used in these experiments was as varied as would be expected in low carbon steel of any purity, and the variations were as follows:

Carbon	0.07	to 0.11	per cent.
Manganese	0.30	to 0.70	per cent.
Sulphur	0.02	to 0.04	per cent.
Phosphorus	0.008	to 0.05	per cent.
Silicon	0.000	to 0.075	per cent.

There were many features of this crystallization in low carbon steel which could not be covered by this investigation, but it is hoped that these results may serve to throw some light on a problem that has remained obscure for so long a time.

Monel Metal's Resistance to Corrosive Action.—Recent experiments made at the laboratory of the Board of Water Supply, New York City, indicate that Monel metal possesses about the same resistance to corrosive action as the better known bronzes, while it had the additional advantage that it presented the least change in appearance as result of the corrosive action. Specimens of several bronzes, Monel metal and steel were weighed and embedded in rich earth which was kept wet for six months by periodical additions of very dilute solutions of corrosive salts. At the end of the test period all of the specimens were taken out, scrubbed, dried and weighed to ascertain the comparative loss from corrosion. The results were as follows:

	Per cent loss.
Phosphor bronze	0.09
Tobin bronze	0.11
Monel metal	0.12
Parsons manganese bronze	0.12
Muntz metal	0.33
Steel	1.04

Another test of the same kind under somewhat different conditions but the same period, gave about the same relative results. Because of its resistance to corrosion Monel metal is now being used in the manufacture of tanks for developing moving picture films.

The production of cyanamide by the American Cyanamide Company, of Niagara Falls, Ontario, is to be increased. The present plant is to be enlarged to more than twice its present capacity, at a cost of $500,000. The company has constantly increased its exports of cyanamide since the beginning of operation in 1910.

The Methods of the United States Steel Corporation for the Commercial Sampling and Analysis of Pig Iron.[1]

Copyright, 1912, by J. M. Camp, Chairman Chemists' Committee.

PREFACE.

In conformity with the design of the officials of the United States Steel Corporation for the standardization of the methods employed in the sampling and analysis of all materials encountered in their various lines of manufacture, the Chemists' Committee presents this compilation of standard methods for the sampling and subsequent analysis of molten pig iron.

In selecting the methods, the committee employed the same line of procedure as in former cases, viz., the careful consideration of all the methods employed in each laboratory of the corporation, evolving therefrom the several methods herein described, the immediate adoption of which is desired.

The services of Messrs. W. B. N. Hawk, Wm. Brady and C. H. Rich, a sub-committee appointed for the preparation of this pamphlet, are gratefully acknowledged.

INTRODUCTION.

A quite obvious cause of non-conformity of results of comparative analyses in the various laboratories of the corporation has been an apparent lack of uniformity of method in the sampling and analysis of molten iron.

This condition is particularly apparent with regard to the determination of the sulphur, numerous discrepancies in which would appear to indicate the absence of, and the necessity for, some uniform method of procedure. The estimation of the sulphur by the gravimetric method and the determination of the remaining constituent elements of the iron, are susceptible of a most satisfactory degree of accuracy. The successful issue of the volumetric determination of the sulphur, however, is largely dependent upon the grade of the iron and the conditions under which the test is taken. A disturbing factor in establishing a satisfactory standard of comparative value in such analyses is the loss of uncertain and varying proportions of the sulphur, due to the formation of volatile and difficultly oxidizable organic sulphides, upon solution of white or chilled iron in hydrochloric acid. Comparative tests by a number of chemists of the corporation having shown quite satisfactory agreement in sulphur values as obtained by the evolution method in sand cast and properly taken so-called chilled test samples, it has been decided to adopt for all purposes the more convenient chilled test, which, it is believed, will tend to conserve the desired comparative accuracy. True values may be obtained in the crushed shot sample by annealing the powder in a current of natural gas or under convenient non-oxidizing conditions, but the exigencies of the routine of the works laboratory, as demanded by the conditions necessarily involved in the manufacture of iron and steel, would in most cases prohibit this metallurgical refinement.

The methods of analysis herein described represent the best present-day practice and it is hoped that their adoption will go far toward reconciling those too often variant conditions, convenience of manipulation and accuracy of result.

The solutions as prescribed are indicated in their various proportions on a 1-litre basis. It will be found convenient, however, in most cases to employ in actual practice corresponding multiples of a greater volume.

Sampling.

Character of the Sample.

Two optional methods are prescribed for taking the test:

1. *Plate or Pat Test.*

With a suitable hand ladle a portion is dipped from the stream of molten iron and, with the spoon of the ladle resting upon a clean, dry iron plate, a pat of such size as may be desired is poured thereon.

2. *Chilled Mold Test.*

With the spoon of the hand ladle resting upon the dry, clean mold (later to be described) a portion is poured sufficient to fill the mold.

The use of the water shot sample is to be considered as in violation of the standard method. The sand cast sample may be used, but the uniform adoption of the pat or the chilled mold test is urged.

Number of Samples to be Taken.

As tending to a reasonable degree of accuracy, it is recommended that a portion be secured, timed as nearly as may be practicable for the middle of each ladle of iron representing the cast. Equal portions from each of these samples are conveniently combined for the subsequent analysis.

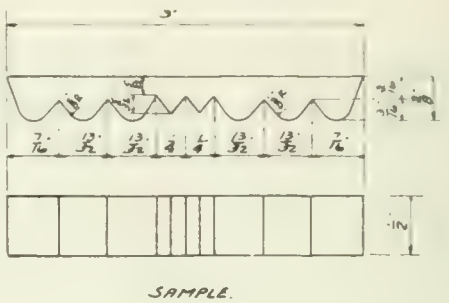
Preparation of the Sample.

The tests are either drilled or crushed as required. If crushed, only that portion passing an 80-mesh sieve is used for the subsequent analysis.

Description of the Mold.

Two convenient forms of mold are recommended, either of which may be used to advantage.

The mold (Fig. 1) furnishes a test which may be conveni-



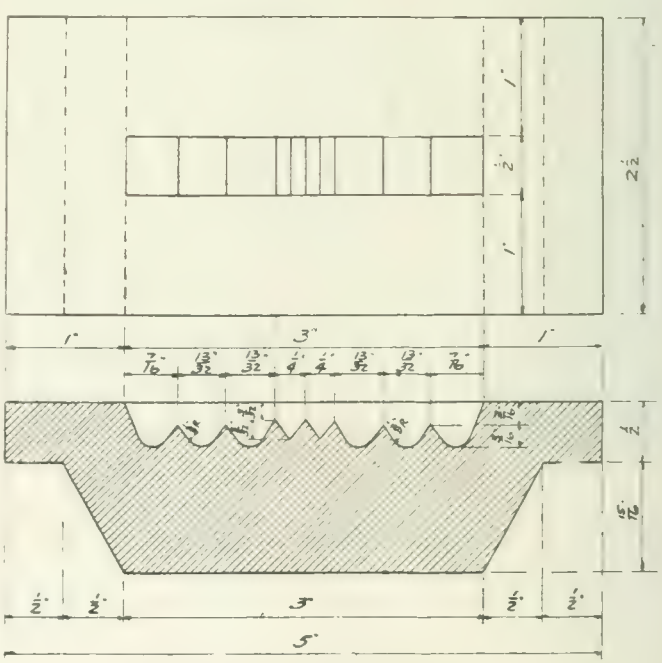


FIG. 1.—IRON MOLD AND TEST.

ently broken and crushed. The number of the furnace may be cast in the mold with Roman numerals or any other suitable form of designation. The two ridges shown in the test in this figure indicate that the test is taken from furnace No. 2.

The mold (Fig. 2) furnishes a test which may be either drilled or crushed. If the sample is to be crushed, the notched

[1] A paper presented at the Eighth International Congress of Applied Chemistry, September, 1912.

prolongation "I" is broken and crushed and the main body of the test reserved for the furnace man's fracture test. The furnace number may also be indicated in this form of mold in the same manner but not so conveniently, and only in the main body of the test.

The molds are made of cast iron and are illustrated in detail, with complete dimensions, in Figs. No. 1 and No. 2.

Methods of Analysis.

Determination of Silicon.

Drown's Method.

A single or double factor weight, .4693 or .9386 gram, of the sample is transferred to a glazed porcelain dish, 15 to 25 cc. of the silicon mixture added, gentle heat applied to the uncovered dish, and the solution is evaporated to pronounced fumes of sulphuric anhydride. The dish is removed from the heat and allowed to cool, the residue is moistened with 10 cc. of the dilute hydrochloric acid, 50 cc. of hot water added and the solution heated without boiling until the soluble salts dissolve. The residue of silica and graphite is collected on a 9 cm. ashless filter, washed alternately with hot dilute hydrochloric acid and water to the disappearance of the soluble iron, and finally with hot water until free from chlorides. The residue is ignited uncovered in a weighed crucible at a moderate temperature until the carbon is completely oxidized, and finally for a few minutes at a higher temperature to the dehydration of the silica. The residual weight in milligrams divided by 10 and corrected in conformity with the initial weight of the sample equals per cent silicon.

Ford's Hydrochloric Acid Method.

This well-known method is useful in point of rapidity, yielding satisfactory results in a shorter time than the more refined Drown's method. A single or double factor weight of the sample is transferred to a porcelain or platinum dish with cover glass, 20 or 30 cc. of concentrated hydrochloric acid added and the solution boiled rapidly to complete dryness; the residue is not baked. Ordinarily, decomposition is complete by the time the evaporation is effected. To the dry residue in the platinum dish there is added at once, or in the porcelain dish when sufficiently cooled, 20 cc. of the dilute hydrochloride acid. The solution is heated gently for a few minutes with the addition of 50 to 60 cc. of water, and the heating continued until the soluble salts dissolve. The residue is collected and finally weighed as in the previously described Drown's method. The use of suction in the filtrations and the ignition of the residue in an atmosphere of oxygen will be appreciated as factors affecting the rapidity of the analyses in both of the above methods.

SOLUTIONS REQUIRED.

Silicon Mixture.		
Nitric acid	1.20 sp. gr.	750 cc.
Sulphuric acid	1.50 sp. gr.	250 cc.
Dilute Hydrochloric Acid.		
Hydrochloric acid	120 sp. gr.	500 cc.
Water		500 cc.

Determination of Sulphur.

Volumetric Method.

Evolution Iodine Titration.

It is apparent that the evolution method is of comparative value only and is in no sense to be regarded as yielding the exact measure of the sulphur content of the iron, a fact of which due cognizance should be taken by all users of pig iron. Equally apparent, however, is the undoubted usefulness of the method in connection with the routine requirements of the iron laboratory and of the various metallurgical processes in conjunction with which it is used.

The apparatus as recommended for this determination consists of a flask of suitable form and size, preferably 16-ounce Florence ring neck with a two-hole rubber stopper equipped with an ordinary funnel or thistle tube and a short piece of glass tubing bent at right angles (exit tube) in the respective apertures. The exit or delivery tube is connected with the absorption vessel in such manner as to conduct the evolved gases to the bottom of the vessel. The absorption may be effected either in the beaker in which the titration is to be conducted, or in a test tube, preferably 10 in. by 1 in., suitably supported.

A minimum of 2.5 grams or a maximum of 5 grams of the sample is transferred to the flask, the stopper is inserted and the flask conveniently connected with the vessel containing the absorbent; 40 to 60 cc. of dilute hydrochloric acid are introduced through the funnel and heat applied, a brisk evolution of the gases being maintained until the powder is decomposed. The temperature is then raised until the steam formed has forced the last trace of the hydrogen sulphide gas into the absorbent. The heat is removed, the apparatus disconnected and the titration conducted.

Ten cc. of the starch solution are added to the titrating beaker and the contents of the absorption tube transferred

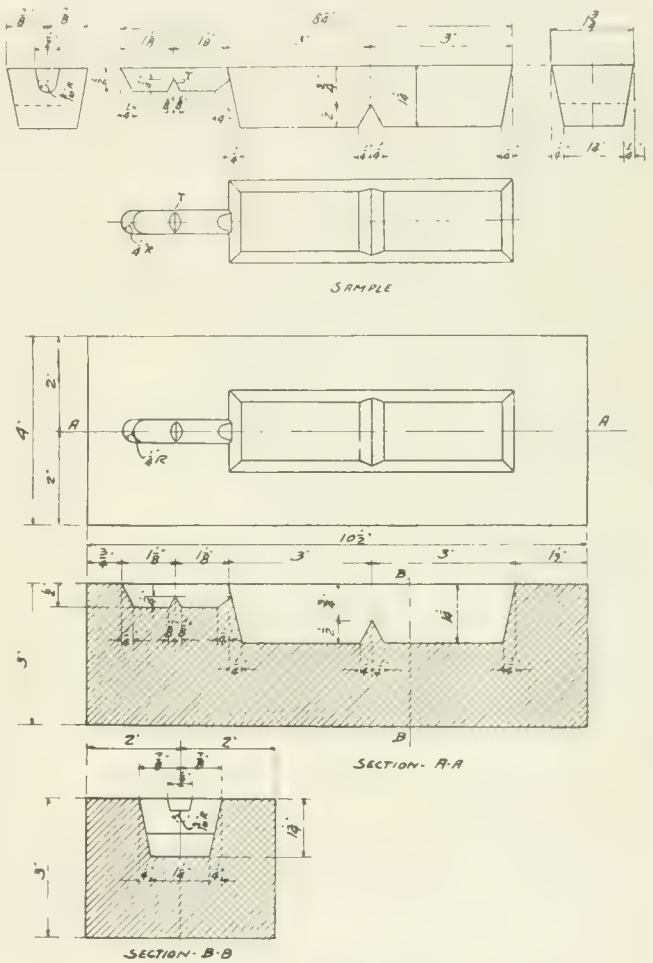

FIG. 2.—IRON MOLD AND TEST.

thereto. Both the absorption and delivery tube are rinsed with cold water and any adhering precipitate is dissolved by means of a fine jet of the dilute hydrochloric acid. Care is exercised that the acid solution be not unduly agitated before the introduction of the iodine solution. If the absorption is effected in the beaker the delivery tube is removed first, cleansed with the acid and water and, with the precaution suggested above, an excess of the dilute acid is added. The final volume of the solution should approximate 400 cc. The solution is stirred gently in order to neutralize the alkali of the absorbent, which, if left undisturbed, reacts with the iodine with formation of a substitution product from which the iodine is but partially liberated upon acidifying the solution. The iodine solution is then added in successive portions, while the solution is stirred

as the color fades, until the addition of a final drop yields the permanent blue color of the adopted endpoint. The number of cubic centimeters of the iodine required multiplied by .01 is equivalent to per cent sulphur.

The volume of the solution in the absorption vessels is so adjusted as to insure a sufficient body for the absorption of all of the gas, and a sufficient excess of the stock absorbent is maintained in proportion to the total volume of the solution. The proportions as used in the 10-in. by 1-in. test tube (15 cc. of any of the stock absorbents diluted to 60 cc.) may be taken as a basis therefor. If desired, the starch indicator solution may be added to any of the stock absorbent solutions in such proportions as to furnish the equivalent of 10 cc. of the indicator in the titration.

Solutions Required.

Starch Indicator.—To 1 litre of boiling water in a suitable flask, a cold emulsion of 6 grams of starch suspended in 100 cc. of cold water is cautiously added, and the boiling continued five minutes after the final addition. The solution is cooled to room temperature, and, with the addition of 6 grams of zinc chloride in 50 cc. of cold water, mixed thoroughly and set aside for a day or two with occasional shaking. After the final subsidence of the heavier residue the starch solution is siphoned into the container and the settlings rejected. The zinc chloride is added as a preservative. Preliminary boiling of the water tends to lessen the frothing or formation of large bubbles on the addition of the starch.

Standard Iodine.—Ten grams of potassium iodide crystals, followed by 4.5 grams of resublimed iodine, are transferred to a glass-stoppered graduated flask; 25 cc. of cold water are added and the flask is shaken until the iodine is completely dissolved. The solution is diluted to volume of 1 litre and set aside for not less than 24 hours before standardizing. The known sulphur of a standard steel, as determined both by the evolution and oxidation methods, is used as the basis of standardization with final adjustment so that 1 cc. is equivalent to .01 per cent sulphur on the basis of the weight of sample used.

Dilute Hydrochloric Acid

Concentrated Acid	500 cc.
Water	500 cc.

Absorbents.

Ammoniacal Solution of Cadmium Chloride

Cadmium Chloride	5 grams
Water	375 cc.
Ammonia	625 cc.

Caustic Alkali

Caustic Potash or Soda	5 grams
Water	1,000 cc.

Ammoniacal Solution of Zinc Sulphate

Zinc Sulphate	10 grams
Strong Ammonia	625 cc.
Water	375 cc.

Gravimetric Method.

Five grams of the sample are transferred to a clean No. 4 beaker or twelve ounce Erlenmeyer flask, and with the addition of 100 cc. of concentrated nitric acid, gentle heat applied until solution is complete. It is sometimes necessary to check a too violent action of the acid, which might result in loss of unoxidized sulphur, by placing the beaker or flask in cold water. The solution is boiled briskly to low bulk, and after cooling somewhat, 30 cc. of strong hydrochloric acid added, the solution is again concentrated, and following the precautionary addition of one gram of pure sodium carbonate, transferred to a clean porcelain dish and evaporated to complete dryness and the residue baked a short time at a moderate temperature.

The dish is allowed to cool, 35 cc. of concentrated hydrochloric acid added and heat applied until the soluble salts dissolve; the solution is again evaporated to complete dryness and the residue baked as before. This procedure insures the elimination of the nitric acid. The dish is cooled, 35 cc. of concentrated hydrochloric acid are added and heat is applied until the soluble salts are again dissolved. The cover is removed, and with the dish placed upon a suitable asbestos ring in order to prevent the formation of a crust of the metallic salts upon the sides, the solution is evaporated to the first appearance of the separation of the chlorides, which are then dissolved by the addition of a few drops of concentrated hydrochloric acid; three drops should suffice. Cold water is added to volume of about 75 cc., the residue is collected upon an 11 cm. filter and the filtrate received in a No. 2 beaker. The residue and filter are washed with the least possible amount of the hot dilute hydrochloric acid, alternated with cold water, to the disappearance of the iron stains and finally with hot water to volume of about 200 cc. To this cold solution 10 cc. of a 10 per cent solution of barium chloride are added and the solution is allowed to stand with occasional stirring not less than twelve hours.

When the precipitate of barium sulphate has subsided, it is collected upon a 9 cm. close ashless filter, washed with dilute hydrochloric acid (5 per cent) to the disappearance of the iron and finally with hot water until free from chlorides. The filter and residue are ignited uncovered in a weighed crucible at a moderate temperature to the disappearance of the carbon of the paper and finally at a somewhat increased temperature for ten minutes. The residual weight multiplied by 13.74 and divided by 5 equals per cent sulphur. The filtrate is set aside until satisfied that no further precipitation ensues.

The carbonaceous siliceous residue of the original solution usually retains some sulphur and is ignited in platinum under cover of pure sodium carbonate and decomposed by fusion with further addition of the carbonate and two-tenths gram of nitre; the subsequent hydrochloric acid solution is freed from its silica and added to the original filtrate, or examined separately for sulphur.

It is apparent that absolute purity of reagents and cleanliness of utensils and the final weighing of the barium sulphate effected under the most exact conditions, are determining factors in the successful issue of analyses by this method.

Determination of Phosphorus.
Volumetric Method.

Acid Alkali Titration

One or two grams of the sample are transferred to a flask, preferably twelve ounce Erlenmeyer, 40 cc. of nitric acid (1.13 sp. gr.) added and heat applied until the sample is decomposed. The sides of the flask are washed down, one gram of ammonium persulphate is added and the solution boiled until the combined carbon is completely oxidized. The residue is caught on an 11 cm. filter and washed with dilute nitric acid (two per cent) and hot water to the disappearance of the soluble iron. The filtrate is heated to boiling in a suitable flask, a slight excess of a solution of potassium permanganate added and the boiling is continued until the excess of the permanganate is decomposed. The resultant precipitate of manganese dioxide is reduced to its soluble nitrate by means of the chosen reducing agent and the boiling continued until the excess thereof is decomposed.

With the solution at a temperature of 80 deg. C., 40 to 60 cc. of ammonium molybdate solution are introduced and the flask is shaken for five minutes. The precipitate quickly subsides and is at once collected upon a 9 cm. filter, washed with dilute nitric acid (two per cent) until free from iron, and then with solution of potassium nitrate (one per cent) to the removal of the last trace of free acid.

The titration may be conducted in a beaker or in the flask in which the precipitation was effected. Care is exercised in the latter case to wash the flask thoroughly with the neutral wash, as any acid present of course reacts with the standard alkali. The filter and precipitate are transferred to the beaker or flask and the standard alkali is added in excess sufficient to render

easy the subsequent maceration of the filter, which is accomplished by breaking up with a clean glass rod, or, if in a flask, by shaking the flask closed by a clean rubber stopper. When the precipitate has dissolved and the paper is thoroughly disintegrated, the solution is diluted and three drops of the indicator are added. The standard acid is then added to the disappearance of the pink tint, the sides of the titrating vessel washed down with cold water and, with a final volume of about 150 cc., the standard alkali is added to the adopted pink endpoint. The number of cubic centimeters of the alkali used in excess of the acid, multiplied by .01 or .02, is the equivalent of phosphorus in hundredths per cent.

Solutions Required.

Standard Caustic Soda.—Six and six-tenths grams of pure sodium hydroxide are dissolved in 100 cc. of boiled water. The solution is freed from any carbonic acid introduced by the caustic alkali, by the addition of about 1 cc. of a saturated solution of barium hydroxide with subsequent filtration, and the solution finally diluted to volume of one litre. If desired, a stock solution may be carried, a convenient aliquot portion of which is diluted for the working solution.

Standard Nitric Acid.—Ten cc. of concentrated acid diluted to one litre. The acid and alkali solutions are standardized against the known phosphorus of a standard steel with final correction so that they are exactly agreeing and 1 cc. is equivalent to .01 per cent phosphorus on the basis of two grams of the sample.

Ammonium Molybdate.—To 65 grams of molybdic acid (85 per cent) suspended in 142 cc. of cold water in a suitable flask, 143 cc. of strong ammonia are added and the flask is rotated until the molybdic acid is completely dissolved. The solution is cooled and added slowly to 715 cc. of nitric acid of 1.20 sp. gr. while the acid solution is vigorously stirred.

Molybdic acid is at times encountered which fails to yield a permanently clear solution of the ammonium molybdate; the addition of one or more drops of a 10 per cent solution of ammonium phosphate assists in clarifying the solution. The solution is allowed to stand over night, when it is filtered into the container, preferably through purified asbestos and with the aid of suction.

Phenolphthalein.—One gram dissolved in 1 litre of ethyl alcohol.

Nitric Acid (1.13 sp. gr.)

Nitric Acid—Concentrated	240 cc.
Water	760 cc.

Potassium Permanganate Oxidant.—Twenty-five grams to 1 litre.

Reducing Agents.

Ammonium Bisulphite.—Five per cent solution.

Ferrous Sulphate.

Ferrous Sulphate	50 grams
Water	1000 cc.

Potassium Nitrite.

Potassium Nitrite	50 grams
Water	1000 cc.

Sugar. Saturated solution.

Potassium Permanganate Titration.

The yellow precipitate as above obtained is washed with ammonium sulphate solution, or if desired, dilute sulphuric acid (2 per cent) until free from iron and molybdenum salts. Dilute ammonia (1 part ammonia and 3 parts water) is poured over the precipitate and the filter is washed with hot water, and the solution caught in the flask in which the precipitation was effected. The volume of the solution should not exceed 25 cc. Eight grams of granulated zinc, 20 mesh, followed by 75 cc. of dilute sulphuric acid are added and the solution is gently boiled until reduction is complete. The undissolved zinc is then collected upon a glass wool filter and both flask and filter are washed with cold water. To the cold filtrate, standard potassium permanganate solution is added until a slight permanent pink tint is obtained. The measure of the permanganate solution required multiplied by its value in terms of phosphorus and divided by the initial weight of the sample equals per cent phosphorus.

Solutions Required.

Acid Ammonium Sulphate.

Strong Ammonia	15 cc.
Sulphuric Acid (1 part acid to 1 part water)	50 cc.

Diluted to 1 litre.

Standard Potassium Permanganate.—Two grams potassium permanganate dissolved in 1 litre of water. One cc. equals approximately .0056 per cent phosphorus on a 1 gram basis. The known phosphorus of a standard steel is used as the basis of standardization.

Gravimetric Method.

Weighing as Ammonium Phosphomolybdate.

One to five grams of the sample are transferred to a No. 5 glazed porcelain dish with cover glass, 25 to 60 cc. of nitric acid (1.13 sp. gr.) are cautiously added, gentle heat is applied until the sample is completely decomposed, and the solution is then rapidly boiled to dryness. The temperature is raised gradually with final heating of the uncovered dish over the full flame of an Argand or Bunsen burner to the complete expulsion of the acid. After cooling sufficiently to avoid danger of breaking the dish, 30 cc. of concentrated hydrochloric acid are added, heat is applied until the soluble salts are dissolved and the solution rapidly boiled to the first appearance of the separation of the chlorides. This evaporation is conducted with the same regard to the prevention of the formation of a crust upon the sides of the dish as in the previously described method for the determination of sulphur. The dish is removed from the heat, 10 cc. of strong nitric acid added and heat again applied for about 1 minute. Cold water is added to volume of about 60 cc., the solution stirred with a clean glass rod and filtered into a suitable flask; the residue, collected upon an 11 cm. filter, is washed with 2 per cent nitric acid and hot water alternately until free from iron, which insures also the complete removal of the soluble phosphate.

When the iron contains titanium in amount sufficient to interfere with the precipitation of the phosphorus and an exact determination is required, the residue of silica and graphitic carbon is ignited in a platinum crucible, the silica volatilized with hydrofluoric acid in the presence of a few drops of sulphuric acid and the resultant residue ignited and fused with sodium carbonate. The melt is boiled with hot water until disintegrated, the insoluble titanate is collected upon a filter and the soluble phosphate added to the main solution.

To the clear filtrate with a volume of about 150 cc., 25 cc. of strong ammonia are added at once and the flask is shaken until the resultant precipitate has coagulated. The addition now of 25 cc. of strong nitric acid renders the solution clear and furnishes an excess of about 10 cc. of strong nitric acid—which, it is found, yields a pure crystalline precipitate of the phosphomolybdate with no tendency to creep. The relatively large amounts of ammonia and nitric acid added are prescribed in the case of 5 gram samples and are essential in that they insure a sufficient proportion of ammonium nitrate in the solution. It is evident that these additions may be decreased with smaller initial weights of the sample, but it will be found advantageous to maintain approximately the excess of 10 cc. of the nitric acid.

With the solution at a temperature of 80 deg. C., 50 to 75 cc. of the molybdate solution are introduced and the solution agitated for about five minutes. When the yellow precipitate has finally subsided, it is collected upon a previously dried and weighed 9 cm. filter, the filter and contents are washed thoroughly with 2 per cent nitric acid, dried for one hour in an air bath at a temperature of about 115 deg. C. and weighed between watch glasses with ground edges and enclosed in a suitable clip. It is of course essential that the light weight of the

previously dried paper shall have been obtained under the same conditions. The increase in weight multiplied by 1.63 and divided by the initial weight taken is equivalent to per cent phosphorus.

Weighing as Magnesium Pyrophosphate

The yellow precipitate as above obtained is dissolved on the filter with hot ammonium citrate solution and the filter thoroughly washed with hot water, and the solution retained in a No. 0 beaker. To this cold solution, 5 to 10 cc. of the magnesia mixture are added, the solution is well stirred and allowed to stand in the cold not less than three hours. The precipitate of magnesium phosphate is collected upon a 9 cm. close ashless filter, washed with dilute ammonia, ignited at a low temperature to the disappearance of the carbon of the filter and finally for ten minutes at the full temperature of the blast. The weight of the magnesium pyrophosphate multiplied by 27.87 and divided by the initial weight taken is equivalent to per cent phosphorus.

Solutions Required.

Ammonium Citrate.

Citric Acid	50 grams
Strong Ammonia	350 cc.
Water	650 cc.

Magnesia Mixture.

Magnesium Sulphate	84 grams
Ammonium Chloride	250 grams
Water	665 cc.
Ammonia	335 cc.

Dilute Ammonia.

Strong Ammonia	200 cc.
Water	800 cc.

Determination of Manganese.

Walters' Color Comparison Method.

Fifty to two hundred mg. of the sample are transferred to a suitable tube or flask, preferably an 8-in. by 1-in. test tube or a 2-oz. Erlenmeyer flask, 10 cc. of nitric acid (1.20 sp. gr.) added and heat applied either in a water bath or on a hot plate until the sample is decomposed. About one-half gram of moist ammonium persulphate, or its equivalent solution, is added and the heating continued until the combined carbon is completely oxidized. If silica or graphitic carbon separate in amount sufficient to render it necessary, the solution is filtered into a similar vessel and the residue retained on a small filter. The filter and residue are washed with the minimum of water, or the 15 cc. of silver nitrate solution required for the subsequent oxidation. The silver nitrate is introduced either through the filter or into the unfiltered solution, one gram of moist persulphate is added and the heating continued until the characteristic pink tint of the permanganic acid is well defined. The solution is cooled, transferred to the comparison tube and the color matched against a suitable standard which has been treated in exactly the same manner and with the same relative initial weight. The relative volume of the solution as required to match the color of the standard is equivalent to hundredths per cent manganese.

Volumetric Method.

The solution of permanganic acid is transferred to a beaker or flask, and following the addition of 10 cc. of sodium chloride solution, the standard sodium arsenite is added to the definite end point of the disappearance of the pink tint. The volume of the solution should not exceed 75 cc. If the silver is not precipitated, the reaction of the persulphate with the silver nitrate renders the endpoint somewhat fleeting and recurring. If conducted without delay, however, the titration may be accomplished with perfect satisfaction. The end point in this case while not so permanent is perhaps somewhat sharper than in the presence of the chloride.

When desired, a greater initial weight of the sample may be taken, the solution thereof diluted to a definite volume, the graphite and silica allowed to subside and aliquot portions withdrawn with a pipette.

Solutions Required.

Sodium Chloride.—Two and one-half grams sodium chloride to 1 litre of water.

Silver Nitrate.—About 66.5 grams of silver nitrate are dissolved in 1 litre of water. Twenty cc. of this diluted to 1 litre affords a solution of which 15 cc. is equivalent to approximately .02 gram of silver nitrate.

Sodium Arsenite.—A stock solution is prepared by dissolving 10 grams of C. P. arsenious acid in a boiling aqueous solution of sodium carbonate (30 grams dissolved in 250 cc. of water), with final dilution of the cold solution to volume of 1 litre. Sixty-two and one-half cc. of this solution are diluted to volume of 1 litre for the working solution of which each cc. is equivalent to approximately 1/10 per cent manganese, with an initial weight of 2/10 gram of the sample. The known manganese of a standard steel or iron is used as the basis of standardization.

Ford's Gravimetric Method.

Five grams of the sample are transferred to a No. 5 glazed porcelain dish with cover glass, 75 cc. of nitric acid (1.20 sp. gr.) cautiously added and gentle heat applied until the sample is decomposed, and the solution then rapidly boiled to complete dryness. The residue is baked a short time at a moderate temperature. The dish is cooled, 35 cc. of strong hydrochloric acid are added and heat is applied until the soluble salts dissolve. Cold water is added to approximately 60 cc., the solution is filtered into a No. 5 beaker and the residue caught on an 11 cm. filter and washed with the least amount necessary of hot dilute hydrochloric acid and cold water alternately, to the disappearance of the soluble metallic salts. The filtrate is boiled to low bulk, cooled, 50 cc. of strong nitric acid are added and the solution is again boiled down to low bulk. The evaporation is repeated with successive portions of nitric acid to the complete expulsion of the hydrochloric acid and with conversion of the chlorides to their corresponding nitrates; the evaporation at this point is carried to the first indication of the separation of the nitrates as observed in the formation of a small nucleus of scum floating on the surface of the solution. After the solution has cooled somewhat, 75 cc. of strong nitric acid are added and the solution is again brought to the boiling point. To the boiling solution, crystals of potassium chlorate (five grams will be found sufficient) are cautiously added in small portions from a glass spoon, and the solution is boiled for five minutes.

The solution is allowed to cool before filtering. Filtration is effected through the medium of an asbestos plug held in a carbon filtering tube. The asbestos is prepared for use by heating with aqua regia to remove soluble lime salts and the plug is washed with strong nitric acid before using. The precipitated manganese dioxide on the filter is then washed with successive additions of strong nitric acid (free from nitrous fumes) to the practical elimination of the iron; the acid is added first to the beaker and transferred from thence to the filter. After the final washing, suction is continued until the plug is practically dry, when the rubber stopper carrying the filter is transferred to a clean flask. The filtering tube is filled with one per cent solution of ammonium bisulphite and allowed to stand about one minute, suction is then applied, successive portions of the bisulphite solution being added until the last trace of manganese dioxide is dissolved; the soluble manganese salt is finally washed from the asbestos filter with hot water. The solution is transferred to a No. 4 beaker or, if preferred, retained in the flask, 10 cc. of strong nitric acid added and the excess of the bisulphite decomposed by boiling. The manganese dioxide could be dissolved perhaps more conveniently by means of hot hydrochloric acid, but the use of the bisulphite solution obviates the possible danger of contamination by traces of soluble lime or

magnesia, which in some grades of asbestos seem to be in evidence notwithstanding numerous successive treatments with the hot acid.

The solution is cooled somewhat and ammonia is added to the point of a faint permanent precipitate, followed by the addition of 15 cc. of a 20 per cent solution of ammonium acetate. The solution is boiled two minutes, filtered into a No. 5 beaker and the precipitate of the basic acetate of iron collected on an 11 cm. filter. The beaker or flask and the filter are washed twice with hot water, the precipitate is dissolved with hot dilute nitric acid and the solution returned to the vessel in which the precipitation was effected. The filter is washed with hot water until free from iron and the basic acetate precipitation and subsequent filtration repeated.

To the combined filtrates 5 cc. of glacial acetic acid are added and the solution is again brought to the boiling point; the cover glass is removed, 10 cc. of a 10 per cent solution of ammonium or sodium phosphate added, and with the solution still at the boiling point and with constant stirring, strong ammonia is added to the first appearance of an incipient opalescence. The stirring is continued until the opalescence has developed into the characteristic crystalline precipitate, at which point the addition of the ammonia is continued, drop by drop and with constant stirring, until the total of 25 cc. has been added.

The precipitate is filtered at once upon an 11 cm. ashless filter and washed with dilute ammonia water (2 per cent) until free from soluble salts. The filter and residue are ignited in a weighed porcelain or alundum crucible at a low temperature until the paper is burned off, and finally at a somewhat higher but still moderate temperature for ten minutes.

$$\frac{\text{Residual weight} \times 38.69}{5} = \text{Per Cent Manganese.}$$

Determination of Total Carbon.
Direct Combustion Method.

The direct combustion of the carbon of iron or steel and their various alloys is fast coming to supersede the more tedious wet method. Certain limitations of this most excellent method, however, are to be noted. The inherent difficulty of successfully burning particles of steel of too great mass is apparent. Certain samples of both iron and steel or their alloys have been encountered of such a character as to necessitate the intimate admixture therewith of a finely divided metallic oxide, or, in the case of certain irons, fine drillings of low carbon steel to assist in the oxidation. The powder of the crushed test of white iron requires a somewhat longer time for complete combustion than the drillings from the test of gray iron but with proper care may be burned with perfect satisfaction. An essential requirement in the conditions of the method is the close control of the temperature which should approximate a constant of 1000 deg. C. and should not fall below 960 deg. C. A pyrometer couple will be found convenient in controlling the temperature.

The combustion is conducted preferably in a fused quartz tube in either an electric or suitable gas-fired furnace. A platinum tube may be used but is subject to damage from possible splashing of the oxidized metal and is, moreover, much more expensive than the quartz. The use of litharge or other volatile and easily reducible oxides is, of course, prohibited in the platinum tube. The quartz tube is 24 inches long by three-quarters inch or seven-eighths inch inside diameter, free from seams and selected of uniform diameter. Platinized asbestos, which may be secured at either end by short plugs of platinum gauze, is inserted for a space of five or six inches in the tube immediately following the position to be occupied by the boat. The rubber stopper at the end of the tube may be protected by the insertion of a removable plug of asbestos conveniently enclosed in a thin roll of platinum gauze. Platinum, nickel, alundum, porcelain or clay boats may be used. The dimensions, 3 to 3½ in. long, by ¼ in. deep, ½ in. wide at the bottom, flaring to ⅝ in. at the top, all inside measurements, will be found convenient. Suitable furnaces for either direct or alternating current, with transformers, rheostats, etc., to suit the individual requirements may be obtained of the trade.

The oxygen from the high pressure cylinder under control of the reducing valve is purified by passing through caustic potash solution of 1.27 sp. gr. contained in washing bottles, preferably two arranged in tandem. A glass tube of convenient form and size, filled with granulated zinc, may be connected to the exit end of the combustion tube to retain possible fumes of sulphuric anhydride formed in the combustion of high sulphur irons. When the potash absorbent is used, a calcium chloride drying tube preceding the bulb or bottle is necessary.

Factor weights may conveniently be used in the direct combustion as follows: For the potash absorption and weighing of the bulb, .2727 gram or .5454 gram, where each one-tenth mg. gain in weight of the bulb is equivalent to .01 per cent or .005 per cent carbon respectively. For the barium hydrate absorption, with ignition of the barium carbonate, .304 gram or .608 gram, where each one-tenth mg. of the weight of barium carbonate is equivalent to .002 per cent and .001 per cent carbon respectively. For the titration methods it is convenient to employ for the initial weight even gram multiples, preferably 250 mg. to 500 mg.

One-quarter or one-half gram or the suitable factor weight of the sample is transferred to the boat. The boat is partially filled with ignited alundum depressed in the center in the form of a V about 1 in. in length, and in which the sample is spread in a compact mass. This intimate contact of the particles of iron conserves the heat for the continuous combustion of the carbon. The weighed potash container or the Meyer bulb tube, to which has been added 80-100 cc. of the barium hydroxide solution or 50 cc. of the standard potash solution, is connected with the tube and the boat is carefully pushed to its position in the center of the heat zone. The stopper of the tube is replaced and, with all connections tight, the current of oxygen is started at a rate approximating a continuous bubbling, as observed in the purifying solutions. It is essential that the tube should have acquired the maximum temperature before the introduction of the boat, a condition which will naturally obtain in the case of a continuous routine of combustion.

The first indication of the oxidation is observed in the sudden decrease of the bubbling of the oxygen through the absorption vessel. As the rate decreases the flow of oxygen is somewhat accelerated until the conclusion of the oxidation process as indicated by the recurrence of the rapid flow through the exit; the flow of oxygen is then reduced to the normal rate which is maintained for ten minutes to insure the complete oxidation of all the carbon and the final absorption of the resultant carbon dioxide. The absorption vessel is disconnected, the current of oxygen discontinued and the analysis concluded by either weighing the potash bulb; titrating the standard solution of caustic potash; filtering, igniting and weighing the precipitated barium carbonate; or titrating the excess of the barium hydrate solution with a weak solution of hydrochloric acid and without preliminary filtration.

By Increase of the Weight of the Potash Bulb or Bottle.

The perfectly clean and dry bulb or bottle is at once weighed. The increase in weight as noted in connection with the initial weight of the sample is corrected to per cent carbon.

The potash container is prepared for use by carefully introducing the required volume of the solution, connecting with the apparatus and passing a current of oxygen through the hot combustion tube to the complete displacement of the air in the container. The vessel is disconnected and at once weighed. The weight so obtained furnishes the light weight for the succeeding combustion.

Titration of the Caustic Alkali.

The absorption in this case is effected in a Meyer bulb tube containing 50 cc. of the potash solution, accurately measured.

The contents of the tube are transferred to a flask, the tube is cleansed with freshly boiled water, three drops of the phenolphthalein solution are introduced and dilute hydrochloric acid (one part acid to one part water) carefully added until the color begins to fade. The more dilute standard acid is then added until the addition of one drop just discharges the pink tint. The excess alkali which has not entered into combination with the carbon dioxide has now been neutralized and the solution is ready for the actual titration. One drop of the methyl orange or methyl red solution is added and the standard acid added in successive portions until the addition of one drop causes the characteristic change from the yellow to the rose tint in the solution. The measure of the acid required for this titration minus the equivalent required in the blank titration and multiplied by the carbon value of the solution equals per cent carbon.

If preferred, the titration may be conducted with the phenolphthalein indicator, the measure of the standard acid required to discharge the pink tint being deducted from the blank equivalent and calculated to per cent carbon as above. This method, however, would not appear to offer any advantage over the other and obviously requires more of the standard acid.

The blank equivalent is established by passing the oxygen through the hot combustion tube and into the measured volume of the absorbent solution with final titration as outlined above. The carbon value of the acid solution is established by titration of the measured volume of the potash solution following the combustion of a standard steel. Additional confirmation may be had by titrating against a standard solution of sodium carbonate. The use of sodium oxalate in this connection is recommended.

Solutions Required.

Standard Acid, one-sixth normal. Fifteen cc. hydrochloric acid (1.20 sp. gr.) diluted to 1 litre.

Caustic Potash, one-sixth normal. Nine and one-half grams diluted to 1 litre. This solution need not of necessity be absolutely one-sixth normal.

Phenolphthalein. One gram dissolved in one litre of ethyl alcohol.

Methyl Orange. One gram dissolved in 1 litre of water.

Methyl Red. One gram dissolved in 1 litre of ethyl alcohol.

Filtration and Ignition of the Barium Carbonate.

The bulb tube is detached from the train, the index finger of the left hand being simultaneously placed over the exit end in order to prevent the solution from flowing back in the tube. The solution is filtered through an 11 cm. ashless filter, the filter and precipitate are washed with freshly boiled water (six good washings will be found sufficient), ignited in a weighed platinum crucible at a moderate temperature to the disappearance of the carbon of the filter and finally at a good full heat for five minutes. The weight of the barium carbonate multiplied by 6.08 and divided by the weight taken, or with correction in agreement with the initial factor weight, is equivalent to per cent carbon. The solution and precipitate are transferred to the filter either by way of the bulb entrance with control of the flow by the index finger upon the open exit end of the tube or by control with the thumb placed over the bulb entrance with the solution poured through the exit end. The precipitate may be readily removed by shaking the tube after successive additions of the water. The washing is conducted as thoroughly and expeditiously as possible and care is exercised to avoid the passage of air unduly through the filter.

Titration of the Excess Barium Hydroxide.

The bulb tube is detached as before, the solution and precipitate are transferred to a 12-ounce Erlenmeyer flask, and the tube thoroughly washed with freshly boiled water. Three drops of the indicator solution are introduced and the standard hydrochloric acid is added in successive small portions, while the flask is shaken, to the disappearance of the pink tint. The agitation of the solution insures the recovery of any carbon dioxide liberated upon the addition of the acid. The equivalent of the acid required in a preliminary blank titration minus the measure required in the actual titration, multiplied by the factor of the solution as determined by frequent combustions of a standard steel and in agreement with the initial weight of the sample, is equivalent to per cent carbon.

Solutions Required.

Standard Hydrochloric Acid.—Eight cc. of strong hydrochloric acid diluted to 1 litre. Freshly boiled water should be used in making up the solution. One cc. of this solution is equivalent to approximately .05 per cent carbon on a 1 gram basis.

Barium Hydroxide.—Twenty grams of barium hydroxide crystals are dissolved in 1 litre of hot freshly boiled water and the flask covered and set aside to cool. When the solution has reached the room temperature, it is filtered as rapidly as possible through a 25 cm. filter into the container. The solution is preferably withdrawn from the container by means of an overflow pipette in conjunction with a suitable guard tube filled with soda lime or caustic potash solution.

Phenolphthalein. One gram dissolved in 1 litre of ethyl alcohol.

Solution and Combustion Method.

The conditions involved in the operation of this method admit of the employment of a greater initial weight of sample than in the previously described Direct Combustion Method.

One gram, or if the barium hydroxide absorbent is to be used, a ten factor weight (.608 gram) of the sample is transferred to a No. 2 beaker or 4-oz. Erlenmeyer flask; 100 cc. of the solution of copper and ammonium chloride or the potassium salt are added and the covered beaker is placed on a suitable stirring machine or stirred by hand, at a temperature of 60 to 70 deg. C. until in solution; or, if a flask is used, it is placed on a shaking machine or closed with a clean rubber stopper and shaken by hand until solution is complete.

The carbonaceous residue is collected upon a filter of purified ignited asbestos made up in a perforated platinum boat, Gooch crucible or other suitable form of holder. The residue is washed by decantation with dilute hydrochloric acid to the disappearance of color in the washings, then transferred to the filter and washed with cold water until the acid is completely removed. Preliminary drying of the residue is not essential in routine work, but where the refinement of accuracy is desired, it is recommended that the residue be dried in a hot air or steam bath at a temperature of 100 deg. to 105 deg. C. The residue is ignited in a platinum or silica tube, combustion crucible or other form of apparatus and in an atmosphere of pure oxygen or air free from carbon dioxide. The apparatus and the subsequent treatment of this carbonaceous residue may conveniently conform to the description of the method by direct combustion, and the final measure of the carbon established by any of the several optional methods therein described.

Solutions Required.

Copper and Ammonium Chloride.—Three hundred grams of the pure salt are dissolved in 1 litre of boiling water. After cooling, 60 cc. of strong hydrochloric acid are added and the solution is filtered through a purified asbestos plug into the container.

Copper and Potassium Chloride.—One pound dissolved in 1 litre of water, as above, with subsequent similar treatment.

Caustic Potash. (1.27 sp. gr).—Three hundred grams dissolved in 1 litre of water.

Determination of Graphitic Carbon.

One gram or the ten factor weight (.608 gram) is transferred to a No. 2 beaker or a 4-oz. Erlenmeyer flask, 40 cc. of nitric acid (1.13 sp. gr.) added and gentle heat applied until solution is complete. The solution is then boiled for a few minutes, the

residue is collected upon a suitable asbestos or paper filter, washed alternately with hot dilute hydrochloric acid and water until free from iron and finally with hot water until free from acid. If the filtration has been conducted through asbestos filter, the residue may be washed with hot caustic potash solution (1.10 sp. gr.) to remove separated silica. If preferred, a few drops of hydrofluoric acid may be added to the acid solution to dissolve the silica which might otherwise interfere with the filtration.

The analysis may be concluded in either of the following optional ways:

First. The graphitic residue is collected upon a suitable filter, washed with dilute hydrochloric acid and water and ignited in the combustion apparatus, and the measure of the graphitic content established as in the case of total carbon. It will be found convenient in this case to use the ten factor weight of the sample.

Second. The filter and graphitic residue are placed in a crucible and dried to constant weight at a temperature of 110 deg. C., then ignited until the graphitic carbon and the filter paper are completely oxidized and again weighed. The loss in weight minus the weight of the filter paper when used and multiplied by one hundred is equivalent to per cent graphitic carbon on a 1-gram sample.

Determination of Combined Carbon. Indirect Method.

The per cent graphitic carbon as found above subtracted from that of the total yields the measure of the combined carbon. If desired, a direct estimation of the combined carbon may be conducted by the color comparison method.

Color Comparison Method.

The relatively exact chemical characteristics and preliminary heat treatment of the test piece and standard are universally recognized as fundamental bases of accuracy in the determination of the combined carbon of iron or steel by the color comparison method. The universal and continued use of this most convenient method in the analysis of steel products attests its efficiency within the close limits of control possible of attainment in the preparation of the steel standards. The application of the method to the determination of the combined carbon of the various grades of iron is much more limited owing to the larger and varying content of manganese and sulphur, the principal disturbing chemical factors affecting the color of the solution to be compared. It is apparent, however, that with a judicious selection of standards and careful control of all factors involved, the color comparison method may be applied to the determination of the combined carbon content of iron with a quite reasonable degree of accuracy.

The method of procedure as recommended is as follows: One gram of the sample is transferred to a dry clean beaker, flask or tube, as desired. In the presence of graphitic carbon, the use of a magnetized spatula or wire in weighing off the sample is, of course, prohibited. Thirty cc. of nitric acid (1.20 sp. gr.) are added and heat is applied until the sample is decomposed. Graphitic carbon and silica are removed by filtration, and the filtrate retained in a 100 cc. graduated flask or cylinder. The filter is washed with cold water to the disappearance of color; the solution is diluted to volume, thoroughly mixed, and 10 cc. withdrawn with a pipette and transferred to the comparison tube. The color is then compared with the color of the solution of a standard iron in a similar tube and which has been treated in exactly the same manner and with the same relative initial weight. The simple calculation involved in the relative volumes of the two solutions yields the per cent carbon in the sample.

A convenient aliquot portion of the above solution may be employed for the determination of manganese by the persulphate color method.

Determination of Titanium.

Five grams of the sample are transferred to a No. 5 glazed porcelain dish or to a No. 4 beaker, with cover glass; 50 cc. of strong hydrochloric acid are added and the sample is digested until completely decomposed. Practically all of the titanium is said to remain insoluble with the silica and graphitic carbon. The insoluble residue is collected upon an 11 cm. filter, washed a few times with hot water, ignited in a platinum crucible and the silica volatilized with hydrofluoric acid in the presence of a few drops of sulphuric acid. The residue is then carefully ignited to the complete expulsion of the hydrofluoric acid, which if retained prohibits the subsequent colorimetric determination of the titanium.

Should it be desired to determine the usually quite negligible amount of titanium in the filtrate from the insoluble residue, it is recovered as follows: The filtrate in a No. 5 beaker is diluted to 250 cc. and strong ammonia added to the first appearance of a precipitate which slowly dissolves upon stirring. Dilute ammonia (2 per cent) is added to a faint permanent precipitate, which is then dissolved by the addition of 15 cc. of a 10 per cent solution of hydrochloric acid. The precipitate thus formed should dissolve rather slowly following vigorous stirring of the solution. One hundred cc. or more of a 20 per cent solution of sodium hyposulphite are added and the solution in the beaker is stirred until the iron is completely reduced and the free sulphur begins to separate. The solution is then boiled for ten minutes and the precipitated titanic acid allowed to subside and collected upon an 11 cm. filter. The filter and precipitate are washed free from soluble salts with dilute acetic acid (2 per cent) and ignited in the crucible containing the ignited residue from the previously conducted volatilization.

The combined residues are fused with 4 grams of sodium carbonate, the melt is disintegrated by boiling with hot water, and the insoluble sodium titanate is collected upon a 9 cm. filter and washed with hot water containing a little sodium carbonate. Hot dilute sulphuric acid is added to the crucible which is then heated until the titanate is completely dissolved. The filter is spread upon the bottom of a No. 2 beaker, the contents of the crucible transferred thereto, and the crucible washed thoroughly with hot water. The beaker is then heated until the titanium salt dissolves, when the paper is removed and its burden of titanium sulphate returned to the beaker by washing with hot water. The solution is then transferred to the color comparison tube or if necessary to a graduated flask and aliquot portions taken. Shreds of filter paper which may be observed in the solution are removed by filtration.

In the color comparison, 5 cc. of C. P. hydrogen peroxide are added to the solution in the comparison tube and the solution is diluted to a volume yielding a color convenient for the subsequent comparison. A color equivalent to .005 gram of titanium in 100 cc. of solution will be found convenient. Water acidified with dilute sulphuric acid (equal parts acid and water) is then added to the standard tube to a volume allowing of subsequent necessary increase, 5 cc. of the hydrogen peroxide is added and the standard titanium solution added from a graduated burette in successive small additions until the colors agree. The measure of the standard solution required multiplied by its value in terms of titanium and corrected to agreement with the initial volume and weight is equivalent to per cent titanium. If the color of the solution yielded by a convenient weight of the sample is of insufficient depth for an accurate comparison, adjustment may be made as follows: A measured volume of the standard titanium solution, sufficient to furnish the required depth of color is added to the solution being tested and the comparison conducted as above described. The volume of the standard solution required in the comparison minus the equivalent previously added to the test solution is calculated to per cent titanium. The volume of the two solutions must, of course, be identical in the final comparison.

In preparing the standard titanium solution 1.05 grams of ig-

nited C. P. titanic acid are fused with 10 grams of sodium carbonate. The melt is digested with 100 cc. of hot water to the complete solution of the soluble alkali which is then filtered from the insoluble titanate. The residue of sodium titanate is washed with hot water containing a little sodium carbonate and dissolved from the filter with 100 cc. of dilute sulphuric acid (equal parts acid and water) and the solution diluted to 1 litre. The titanium equivalent of this solution is ascertained by igniting and weighing the precipitated titanic acid of an aliquot portion following a separation with sodium hyposulphite as previously described. The ignited salt will be found to contain approximately 95.6 per cent titanic acid. One cc. of the solution in the above proportion will therefore contain 0.6 mg. of titanium.

A gravimetric determination of the titanium in the iron may be conducted in the same manner, but inasmuch as in the colorimetric method the titanic acid as separated need be only relatively free from contamination by occluded salts, it is apparent that the latter method may be used to advantage, especially where many such determinations are required.

Determination of Copper.

Gravimetric Method.

Five grams of the sample are transferred to a glazed porcelain dish, 65 cc. of nitric acid (1.20 sp. gr.) are added and the covered dish is heated until solution is practically complete. Twenty-five cc. of dilute sulphuric acid (equal parts acid and water) are then added and the solution is evaporated to fumes of sulphuric anhydride. Ten cc. of the dilute sulphuric acid followed by 50 cc. of hot water are added, the residue is heated until in solution, and the solution is filtered into a No. 4 beaker and the filter washed with hot water. The filtrate is diluted to 300 cc., heated to boiling and, with the addition of 25 cc. of concentrated ammonium bisulphite solution, the boiling continued to the complete reduction of the iron. Thirty cc. of a 20 per cent solution of sodium hyposulphite are then added and the boiling is continued for five minutes or until the precipitated copper sulphide has coagulated. The precipitate is collected upon an ashless 11 cm. filter, washed with dilute nitric acid (2 per cent) and hot water, carefully ignited and weighed. The weight of the copper oxide as noted, multiplied by sixteen (80 divided by 5) equals per cent copper. Too great a temperature in the ignition causes the copper oxide to fuse on the crucible. As the copper oxide is somewhat hygroscopic, as are also some porcelain crucibles, less error is encountered by igniting in platinum.

The ignited copper oxide carries with it traces of contaminating iron. If it be desired to correct this usually negligible error, the impure oxide is dissolved in the crucible with 10 cc. of strong nitric acid, the solution transferred to a No. 2 beaker and diluted to 100 cc.; the iron is then removed by an ammonia precipitation. The precipitate so obtained is collected upon a 9 cm. filter, washed with hot water, ignited in the crucible in which the previous ignition was conducted and the weight of ferric oxide noted. This weight is deducted from the weight of the impure copper oxide and the correction applied.

Volumetric Method.

The nitric acid solution of the impure copper oxide in the No. 2 beaker obtained as above described, is rapidly evaporated to the removal of the bulk of the free acid, and the solution diluted with cold water to volume of 150 cc. Strong ammonia is then added from a burette until the addition of a final drop causes the permanent bluing of the solution, after which there is added by means of a pipette six drops of acetic acid. Ten cc. of a 40 per cent solution of potassium iodide are added and the standard sodium hyposulphite solution is run in until the color of the liberated iodine has almost disappeared. Ten cc. of the starch solution are now added and the addition of the standard sodium hyposulphite solution is continued to the final disappearance of the blue. The number of cubic centimeters of the standard solution required multiplied by its value in terms of copper and divided by five equals per cent copper in the sample.

The value of the standard hypo solution is determined by titration of a solution of pure copper or by titrating the solution of a steel of known copper content. The apparent large excess of the potassium iodide employed is because of its relation to the final end point in titration, the sharpness thereof decreasing in proportion as the excess of the iodide is decreased; the presence of ammonium salts in the solution also tends to lessen the permanency of the end point, hence the necessity for the preliminary evaporation of the acid solution.

If necessary, the time required for the volumetric determination may be materially lessened by initial solution of the sample in 50 cc. of dilute sulphuric acid (one part acid to three parts water), and the evaporation to dryness and filtration from the silicious residue omitted. The iron in this case not being oxidized, the boiling with the ammonium bisulphite is also omitted. The copper oxide so obtained is contaminated to a greater degree by occluded iron, which if it be present in the final titration is prejudicial to a satisfactory end point. This iron is, however, readily removed by filtration following the evaporation of the nitric acid solution previous to the addition of the ammonia. It is apparent also, that following the nitric acid solution of the sample, the preliminary treatment with ammonium bisulphite in the gravimetric method may be dispensed with, as the reduction may be accomplished by the addition of a sufficient excess of the sodium hyposulphite solution at the time of the precipitation of the copper sulphide. The precipitate formed under such conditions, however, carries an unduly large burden of separated sulphur, the presence of which would appear undesirable.

Solutions Required.

Standard Sodium Hyposulphite.—Eight grams to 1 litre. One cc. is equivalent to approximately .002 gram copper.

Starch Solution.—The solution as used in the volumetric determination of sulphur.

Multiple-deck slime concentrators designed by A. R. Wilfley are being used in some of the large copper mills in place of vanners. The machine consists of a series of concentrating decks, covered with grooved linoleum, and placed above each other. The space between decks is 1¼ in. The even distribution of the ore-pulp and wash water to the several decks is effected by an ingenious device, and is automatic. The table receives a simple longitudinal motion from an eccentric. The cycle of operation is divided into three periods: (1) feeding slime onto the decks, which are in a practically horizontal position. This continues for some minutes, during which the mineral becomes concentrated in the grooves. (2) Passing wash water onto the decks, which have now been tilted at a slight angle, to facilitate the removal of the upper layer of gangue which covers the concentrate. (3) Washing the concentrate out of the grooves and off the decks by means of a sudden flow of water. In this period the decks are tilted at a still greater angle. After a completion of the cycle, the table is returned to a horizontal position, ready for another feed of slime. Twelve decks are thus combined, giving a concentrating space of 864 sq. ft. The capacity of the machine is regarded to be equal to that of 8 vanners, and it requires about the same power and occupies the same space.

Nevada Consolidated Copper Company produced in the second quarter of this calendar year 18,092,439 pounds of copper. There was milled 813,141 tons of ore containing 1.66 per cent copper.

The United States Geological Survey has completed its final compilations showing metal productions in the various western states during 1911. Copies of the work can be had on application to the director, Washington, D. C.

Meeting of Lake Superior Mining Institute

The seventeenth annual meeting of the Lake Superior Mining Institute was held this year in the copper country, with headquarters at Houghton, Mich., on August 28, 29 and 30. In point of interesting papers presented, and large attendance from the copper and iron districts of Michigan and Minnesota, this session of the Institute was one of the most successful in its history. Before the meetings were over nearly 250 members and guests had registered with Secretary A. J. Yungbluth.

Many of the papers had been printed in advance and were distributed before the meeting. The visitors were provided further with a souvenir booklet, compiled by Mr. Arthur L. Carnahan, giving concise general information regarding the copper country, together with a map of the district and a tabulated statement of the mining and milling equipment of the principal copper companies.

Wednesday, August 28.

An afternoon excursion took the visitors first to the Michigan Smelting Works, where they witnessed the tapping of a reverberatory furnace and the casting of copper into various merchantable shapes. A Walker casting wheel is in use here, being the only one at present in the district.

Proceeding by train to the mines of the Copper Range Consolidated Company, the party inspected the power plant, blacksmith and machine shops of the Champion mine. At the Baltic mine interest centered chiefly in the dry and change house and in the sanitary provision which the company has made for the comfort and cleanliness of the men when they come off shift. Although excellent bathing facilities have been provided, the foreign laborers have been slow to take advantage of them; but the company believes that they will gradually become educated to use the baths more frequently and regularly, and ultimately appreciate this provision for their health and comfort.

The concrete oil-house at the Baltic mine is worthy of mention, as it represents an effort to systematize the storage and distribution of lubricants. Economical lubrication is a matter of importance at a large plant, as will be shown later in an abstract of a paper on that subject presented at one of the Institute meetings.

Returning to Houghton, the Institute convened in the evening for the reading and discussion of papers. Most of them related to mining and geology, and showed the keen interest which is being taken in the application of scientific principles to the solution of practical problems. The possible future extension of the copper-bearing area was discussed by Dr. A. C. Lane, of Tufts College, Mass. The proper location of shafts in relation to the copper lodes was presented by Dr. L. L. Hubbard, of Houghton. Other interesting papers presented were: Methods of Sampling at Lake Superior Iron Mines, by Benedict Crowell, of Cleveland, O.; System of Safety Inspection of the Cleveland-Cliffs Iron Company, by William Conibear, of Ishpeming, Mich.; Raising Shaft at Rolling Mill Mine, by E. N. Cory, of Negaunee, Mich.; Mine Sanitatioin, by E. B. Wilson, of Scranton, Pa.; Raising, Sinking and Concreting No. 3 Shaft, Negaunee Mine, by Mr. S. R. Elliott, of Negaunee, Michigan.

Economical Lubrication was the title of a paper prepared by **W. W. Davis,** of Boston, in which the author expressed the opinion that in these days of close attention to operating costs it has been found advisable to give greater care to the selection, storage, distribution and use of lubricants used in any plant of machinery, and especially in connection with large mining, milling and power companies. The paper first discusses the kinds of lubricants and their proper sphere of usefulness, and then takes up the methods necessary to secure economical lubricating costs.

"The selection of proper lubricants depends, of course, upon the class of machinery on which they are to be used. If on light-running and high-speed machinery the light-bodied or more fluid oils will give best results. For slow-speed machinery the heavier bodied oils will be better. For use on slow-speed engines where the oil is fed from cups a heavy-bodied oil should be used. For high-speed work and engines where continuous oiling systems are in use, a light-bodied oil should be used. Cylinder oils have for their base what is known, in the oil trade, as cylinder stock, of which there are two classes, the light colored or filtered stock and the dark or steam-refined stock, the latter being almost universally used. This cylinder stock is high in flash test and viscosity, but of itself would not make a good steam cylinder lubricant under ordinary saturated steam conditions; being a petroleum product, it has no affinity for moisture and will not stick to the wet cylinder and valve surfaces, so it is customary to compound this petroleum stock with a certain amount of fatty oil, usually tallow oil or neatsfoot oil, in order that it will emulsify with the steam and cling to the surfaces. Where the steam is fairly dry, 3 to 6 per cent is usually sufficient. Where the plant is small and the lubricating cost is a small matter, the most satisfactory method of purchasing lubricants would be to buy of some reliable oil firm, but where the cost of lubrication runs into thousands of dollars, as is the case with many corporations, and it is desired to obtain suitable lubricants at the lowest market price, the best plan is to purchase on specifications, stating clearly just what is needed, and awarding a contract for a year's supply to the lowest responsible bidder. Specification buying is fair both to the consumer and the dealer."

Service tests may be made on different oils by noting the rise in temperature in any bearing on a machine which is running under constant load and speed. Thermometers placed in the bearing and in the room near the machine will make it possible to secure data showing the temperature due to friction, and by plotting the results obtained with different lubricants an idea of their efficiency will be gained. In general, it is safe to assume that, of two oils, the one that will keep the bearing the coolest is the best lubricant.

The author emphasizes the necessity of oil-recovery in connection with continuous oiling systems, and gives instances of great waste where elaborate provision has been made for applying the oil, but none for its recovery and re-use. Another point brought out is the loss which occurs in burning oily waste instead of recovering the oil contained therein.

In closing the paper gives directions for the systematic distribution of oils to employees, and outlines a method for keeping accounts. An appendix gives the plans and specifications of the oil-house at the Baltic mine..

Thursday, August 29.

The itinerary for the second day included points of interest north of Houghton, notably the great stamp mills of the Calumet & Hecla Mining Company at Lake Linden. The general features of the milling process here are quite well known; nevertheless there has been enough progress of late to make the plants interesting even to those who had visited them before. The improved system of classifying and jigging which is now in operation is an innovation since the last meeting of the Institute at Houghton. Further, the project to regrind and reconcentrate much of the old accumulation of tailings struck the visitors as conclusive evidence of the improvement in modern milling methods.

At Ahmeek there was a good opportunity to see mass copper of various sizes, just as it is sent from the mine to the smelter. Several carloads of mass were awaiting shipment. One of these consisted of two large pieces of copper, weighing perhaps 15 tons each. Other cars were loaded with smaller masses. Another matter of interest at Ahmeek was a concrete "timber" set, which had been assembled in the position which it would occupy in the shaft. This system of shaft lining is used to the complete exclusion of timber, and presents some possibilities in extending the application of concrete underground. The first cost is less than for timber, and the resulting structure is fireproof and indestructible in ordinary service.

At noon the party enjoyed an hour of recreation at Electric Park, where lunch was served. Proceeding then to Franklin, the mining and mechanical engineers were much interested in watching the operation of the air-balanced hoisting engine which is used on the single-compartment shaft, hoisting ore in 10-ton skip-loads. During the descent of the skip the engine works as an air compressor, storing air in great receivers under an ultimate pressure of about 95 lb. per square inch. When starting to hoist, the compressed air is used as long as available, after which the steam automatically comes on. This arrangement relieves the steam plant of the peak load required to start the hoist and accelerate it to normal speed.

The social feature of the meeting was a dinner at the Onagaming Yacht Club, where the visitors were taken by boat. The Calumet & Hecla band provided music on the boat and rendered an excellent program after dinner.

Bureau of Mines.

The speaker of the evening was **Dr. Joseph A. Holmes,** director of the Bureau of Mines, Washington, D. C., who had come to Houghton at the special invitation of the Institute. Dr. Holmes spoke at some length on the function of the Bureau of Mines and outlined some of the relations which it would and would not have with the mining industry. The pubic welfare is the only basis for the Bureau's work, and unless the results of this work contribute to the public good the activity of the Bureau is not justified.

There are two phases of public welfare which Dr. Holmes thought worthy of the Bureau's attention and within the scope of its plan and purpose. These are public safety and avoidance of waste. On these subjects it is the desire of the Bureau to gather and disseminate all the information which it is possible to obtain, from foreign countries as well as our own. Private or secret information is not sought, neither is it the intention to encroach on the field of private endeavor, but, on the contrary, to maintain that strictly public position which shall make the Bureau useful.

Dr. Holmes stated that as a result of the Bureau's work mine disasters and accidents have been steadily diminishing, although they have not yet been reduced to the desired minimum. It has been the aim of the Bureau to instil into the leaders of the mining industry ideas relating to the safety and discipline of the miners, and to secure their co-operation in making mining less hazardous. Practical instruction is given in handling explosives, and mine rescue work is taught.

On the second phase of his subject Dr. Holmes reminded his audience that conservation of mineral resources did not mean that we should not use those resources to just as full an extent as our conditions demanded, but that it did mean that we should so conduct our operations that great loss of resources would not result. He cited the fact that by our present system of coal mining we waste half a ton for every ton mined; that more natural gas is wasted annually than is produced artificially. These are the greatest examples of mineral waste and need of conservation. An appreciation of the situation is already felt among the metal-mining companies, for a vast amount of low-grade iron ore which is now worthless is being saved in anticipation of the day when it will be needed and when improved metallurgical methods will make it available. Other ores of low grade throughout the West are being conserved and treated, in full realization of the fact that the bonanza days have gone by.

Following Dr. Holmes' address, Mr. M. E. Gow commended the work of the Bureau and advised all present to take advantage of the information contained in its free publications. Mr. Gow then spoke briefly of the welfare work of the Steel Corporation in behalf of its employees.

Friday, August 30.

The closing session of the Institute was held Friday morning at the School of Mines and was devoted to reading and discussion of papers and election of officers.

Recent Rock-House Practice in the Copper Country.

There were two papers presented on this subject; the first was by **Tenney C. DeSoller,** of Hancock, Mich., who described the practice at No. 2 rock-house of the Quincy Mining Company as representing the best procedure which the company has yet been able to devise.

The Lake Superior methods of handling copper rock, as it is locally termed, have undergone many improvements during the past few years, both with respect to underground and surface operations. Past experience has shown that it is advisable to break the rock to a size that can be advantageously fed into the steam stamps at the mill. The material, as it is hoisted to the surface, comes in sizes varying from fine material to large masses of native copper, copper rock and poor rock, weighing at the maximum several hundred pounds.

General Description of Building.

The building is of steel, with corrugated iron roof and sides and reinforced concrete foundations and floors, thus making the building absolutely fireproof. All the bins are of steel and are circular in transverse section. The bottoms of the bins, instead of being built up and costly to maintain, are filled with poor rock until the latter assumes an angle of natural slope, thus making its own bed and causing all copper rock dumped into the bins to discharge through the regular openings. The building is 150 ft. long and 30 ft. wide, except where the large stamp rock bin, 44 ft. in diameter, is located. The crusher floor, situated on top of the stamp rock-bin, 45 ft. above the discharge aprons, is of the same size but square. This bin will hold upwards of 2000 tons. This large capacity takes care of variations in car supply and rate of hoisting.

The skip track above the collar of the shaft has an incline of 54 deg. and the shaft runners are carried up on this angle to the copper rock dump, where there is an outward curve toward the hanging of the shaft for the wider face of the rear skip wheel to travel upon. The 12-ft. wood-filled rope sheaves are located 119 ft. vertically above the collar of the shaft and are securely stayed by means of a batter brace. A room located at one side of the collar of the shaft is occupied by the lander, one of whose duties it is to transmit to the hoist engineer the signals as communicated to him from the underground chute men. The lander, without leaving his room, moves a sliding plate by means of levers which allow an opening for the narrow face of the front skip wheels to pass through onto a track toward the foot of the shaft, the rear skip wheels, which have a wider face, continuing in the plane of the incline and thus dumping the skip.

There are three points of discharging: The first for mass copper and dull drills; the second for poor rock from sinking shaft or bottom level cross-cuts; the third, the regular copper rock discharge. A set of levers, one for the first and one for the second, will permit the opening of the discharge as indicated by the signals. An 8 x 8-in. steam hoist, located in one corner of the building, is for handling timber, cranes and other supplies; also for the track forms used to take a damaged skip or other conveyor from the skip road. The man-cars, water skip and rock skips are suspended from cranes and can be quickly swung into place and put in operation.

Rock Handling.

The rock is hoisted in the two 8-ton skips running in balance. The skips, as before stated, have three discharges. The first discharge handles the large mass copper and dull rock drills. In this dump the skip discharges onto a concrete block faced with old rail (flange up) having a slope of 30 deg. This slope changes to level and forms a platform of the right height for loading the mass copper onto a railroad flat car. Masses weighing up to 8 tons are loaded upon the railroad cars by means of 8-ton chain blocks hung from trolleys in either compartment carried by 18-in., 55-lb. I-beams extending out over the railroad track. The dull drills are easily loaded onto a wagon or car and taken to the drill shop to be sharpened, while the mass copper is shipped directly to smelter.

When poor rock is hoisted from shaft sinking or the bottom level cross-cuts, the second dump is opened by means of the above-described levers and the skip discharges into a reinforced concrete chute, which empties into a cylindrical steel bin 13 ft. in diameter. This rock is drawn off by two chutes, one of which feeds a 24 x 18-in. Blake type rock crusher, where the rock is crushed to a size adapted for concrete or road work. Under the crusher is a cylindrical steel bin 9 ft. in diameter, where it can be loaded from a chute into railroad cars or wagons. The chute on the opposite side of the 13-ft. bin permits the discharge of the coarse rock directly into a vertical cylindrical steel tube 5 ft. in diameter, dropping upon a reinforced concrete block slightly inclined, which breaks the fall, and from which it can be loaded through a chute into railroad cars, or wagons.

When copper rock is hoisted, the third, or regular, discharge is used and was made as above described in order that the lip of the skip might remain in a position close to the steel dumping plate and not cause the rock to be violently thrown from the skip. It might be stated that the copper rock dump was designed in order that the skip should discharge into a pocket which would fill until the rock took its natural slope, the rock then discharging onto the grizzlies. It was found during the erection of the building that there was a mistake of about 3 ft. between the blue prints and the steel construction, and a steel dumping plate was substituted.

The dumping plate spreads the rock on 6-in. steel grizzly bars approximately 16 ft. long, set at 16 deg., and having 20-in. openings. Immediately above the grizzly bars is a battery of heavy bars, which serves the double purpose of breaking the fall of the rock and spreading the same upon the grizzlies. The oversize from the grizzlies passes down on a reinforced concrete chute, striking a second battery of bars, then drops vertically into a bin having its side open toward a 3000-lb. drop hammer. Between bin and hammer is a 15-in., 42-lb. I-beam carrying a traveling 8-in. 2-ton air lift. This I-beam is bent in the shape of a horseshoe and permits the air lift to be used at either crusher, or poor rock chute. Here the oversize, if mass copper, is cleaned of the poor rock under the hammer; if copper rock, it is broken to a size that can be handled by the crushers; or, if poor rock, it is thrown into a chute leading to the poor rock bin.

In case the broken oversize is small mass copper, it is thrown into a mass copper chute leading into a cylindrical steel bin 6 ft. 8 in. in diameter, which discharges into railroad cars. If it is mass copper too large for this chute, it is loaded onto a pan, swung from a crane, and lowered outside the building to a reinforced concrete platform at the right elevation for loading on a railroad flat car.

The undersize from the 20-in. grizzlies falls upon a second grizzly composed of 3½-in. steel bars, 6 ft. long, set at 30 deg., and having 2¾-in. openings. The undersize from these last grizzlies passes directly into the stamp rock bin below the crusher floor. The oversize is discharged into a cylindrical steel bin 14 ft. in diameter holding approximately 10 skip loads of rock. The outlet from this bin is by two chutes 19 ft. apart. Vertically sliding steel doors, 4 x 4½ ft., with replaceable steel linings, operated by 6 x 36-in. air cylinders, control the feed into steel chutes set at 30 deg. This feed is directed into the two 36 x 24-in. Blake type rock crushers and regulated by a hinged apron, which is operated by a 6 x 18-in. air cylinder. One man at each chute feeds the crusher, picks out the poor rock and mass. The poor rock goes into a chute leading to the poor rock bin. The mass is stored upon an inclined semicircle chute called the "copper pan," on which it easily slides to a small steam hammer, is cleaned from poor rock, and thrown into a chute leading to the mass copper bin. This steam hammer is run by a third man who handles the trolley already described, cleans the mass copper, oils, and has charge of the machinery.

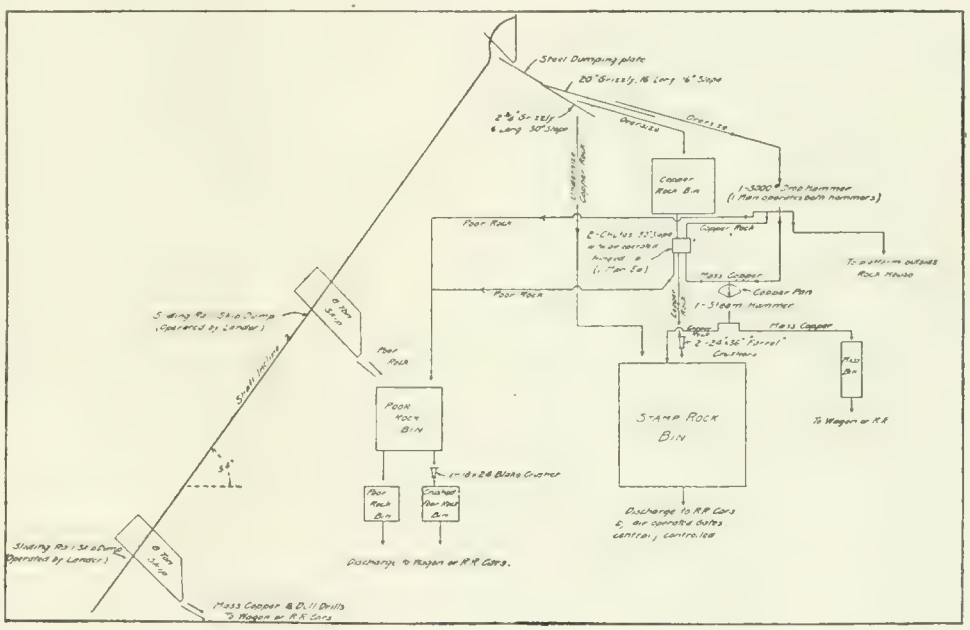

FIG. 1.—FLOW SHEET OF ROCK HOUSE NO. 2, QUINCY MINING COMPANY, HANCOCK, MICH.

The crusher jaws are made of manganese steel, and are set to crush to 3 in. The crushers, running at 140 r.p.m., are operated by a 12 x 24-in. Nordberg Corliss-valve steam engine running at 110 r.p.m. A 75-hp electric motor occupying less space is installed, and is ready to run in case of a breakdown to the engine..

The rock from the stamp rock bin is loaded into railroad cars for the mill by means of discharge aprons operated by 5 x 13-in. air cylinders.

Three men handle upwards of 1000 tons of rock every 12-hour shift, change man-cars and skips on skip-road and load all timber and supplies that are lowered underground. Between shifts, when the large mine air compressors are not in operation, power for the operation of the air lifts and air controls is furnished by a small 11 x 11 x 12-in. Westinghouse air pump, so arranged that when the air pressure from the mine compressor drops, the air pump automatically starts. A com-

bination of check valves prevents loss of this air into the underground system and, likewise, when the air from the compressor is raised, the air pump is automatically stopped. This system of handling material has shown an average rock house cost of less than two cents per ton.

Rock-House Practice at Copper Range Properties.

The second paper was by **H. T. Mercer,** Painesdale, Mich., who described the practice of the Copper Range Consolidated Company. Mr. Mercer first reviewed the early practice, showing the development of the dumping system from the time when ore was hoisted in 2½-ton skips to the present time when 6-ton skips are used.

In our old rock houses, the rock on leaving the skip dropped on an iron door about 5 ft. long, set at an angle of about 30 deg., below which, set at the same angle, were the screen bars, or grizzlies. The iron door was hinged at the lower end and could be raised to allow for the dumping of waste rock into a separate bin or car, underneath the skip track.

The grizzlies were first constructed of 4-in. round iron bars, about 12 in. long, set 4 in. apart. These were later discarded in favor of 3 x 10-in. hardwood bars capped with 1 x 4-in. iron straps. The latter were cheaper and easier to replace than the round bars. At the lower end of the screen was a 4-ft. drop to the floor, and at this point in the floor several bars, or rails, were inserted, set 4 in. apart, at right angles to the grizzlies, forming a floor screen. Any fine dirt that had failed to drop through the grizzlies could be shoveled through this floor screen to the storage bins below.

The crushers used at that time were of the jaw pattern, 18 x 24-in. in size, and ran at a speed of 85 to 90 r.p.m. There were two of these crushers, one in front of each grizzly, and about 12 ft. away, the floor between the crusher and the grizzly being paved with heavy plates. This long space was to allow for sorting and picking of mass, but necessitated a great deal of shoveling to get the rock to the crushers. The mass copper was picked out and taken, by hand, across the floor to a drop hammer, where the surplus rock was pounded off. It was then thrown through a chute to the ground, where it was collected and teamed to a central point, to be loaded onto a car and shipped to the smelter. Pieces of rock too large for the crusher were also taken to the hammer and broken. The finer pieces resulting were dropped through an opening in the floor to the bins and the large pieces taken back to the crushers. Beneath the crushers were the large storage bins, from which the rock was loaded into cars by means of the ordinary apron chutes operated by separate hand levers. Any waste sorted on the crusher floor was transferred by hand or barrow to the poor rock car, which ran on a track a little below the level of the main floor. Most of the waste, however, was hoisted separately, dumped directly into the poor rock car and trammed out on to the waste rock pile by the rock house crew.

Such, briefly, were the methods in use ten or twelve years ago. Let us turn now to the newer method and see what has been accomplished. In the following description, reference is made to Fig. 2:

In the first place we have done away entirely with the grizzly. On leaving the skip the rock drops directly into a large bin, capable of holding about 20 or 25 skip loads. In the front side of this bin there are two sliding doors, one in front of each dump, each operated by an 8-in. air lift. These doors are 5 ft. wide and 5 ft. high and are lined with 2-in. cast-iron plates. The front of the bins above the door is also lined with iron to protect the wall from the impact of the rock. The bottom of the bin is about 2 ft. below the bottom of the doors and this space is filled with waste rock until it takes its natural slope to the door. No paving is used except near the door, where a heavy iron plate projects into the bin at an angle of 30 deg., to help in starting the rock through the door. Outside of the bin in front of each door is an apron or chute about 4 ft. long, set at 30 deg. The lower end of the chute rests directly on the jaw of the crushers, which are Farrell type 24 x 36 in. in size, run at a speed of 155 to 185 r.p.m. They are designed for as high as 300 r.p.m. There are two of these crushers, one in front of each door. Each crusher has a capacity of from 500 to 1000 tons daily. Fastened to a shaft on the top of the crusher, by means of arms, is a cradle or gate, which drops into the lower end of the chute. This gate is operated by a 4-in. air lift. The operation of feeding the rock to the crusher is as follows:

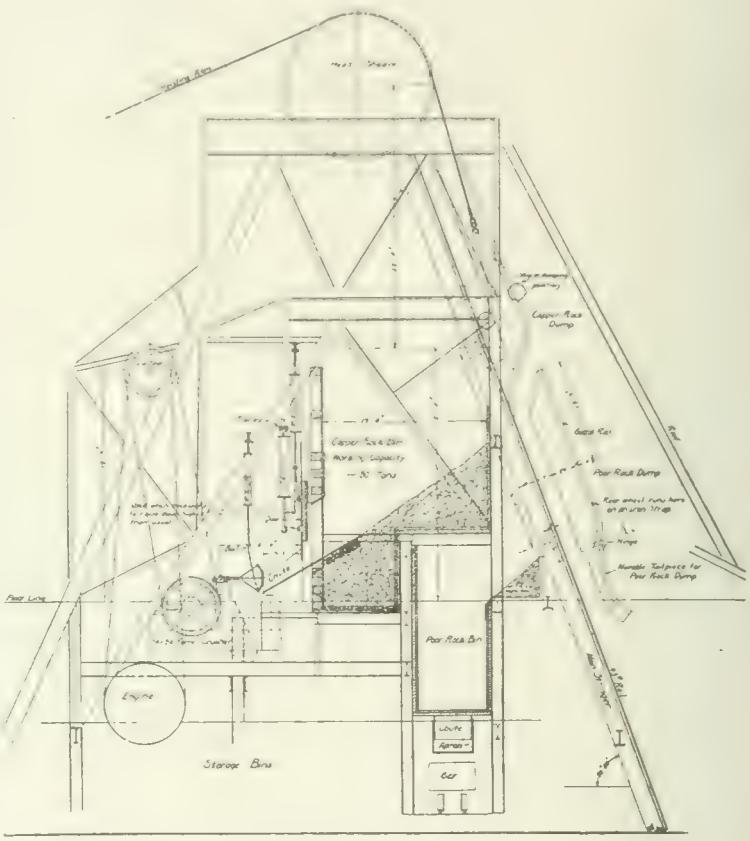

FIG. 2.—SECTIONAL ELEVATION OF ROCK HOUSE OF THE CHAMPION COPPER COMPANY.

When the bin door is raised the rock runs down into the chute and is stopped at the crusher jaw by the cradle gate. The bin door is then shut and any mass or large boulders that may have come down are sorted out. Then the gate is raised and the rock feeds directly into the crusher with little or no handling. A trolley, carrying a 10-in. air-lift, runs directly over the chutes in front of the crushers, and by this means the mass and large rocks are quickly picked up and transported to the drop hammer, which is set at one end of the building, and operated by a small electric hoist. On leaving the hammer the mass is pushed through a door in the side of the building and drops straight down to a platform alongside of the railroad track. This platform is built of log cribbing filled with waste rock, the top being at the same elevation above the track as an ordinary flat car. Hinged on the side of the rock house above the car platform, in such a position that it swings out over the car, is a simple jib crane, built of an 8-in. I-beam, 10 ft. long. On this beam runs a trolley to which a chain block can be attached. By this means the mass copper is easily loaded onto the car. The larger masses are picked up with a chain, and an iron pan swinging on chains, is used for the smaller pieces. No sorting of poor rock is done in the rock house. All waste

hoisted is dumped into a separate bin by means of a lower hinged dump such as has already been described. From this bin it is loaded into a car trammed out on a trestle and dumped through a raise into the old stopes.

At several of our shafts where the poor rock trestle is of sufficient height bins have been built near the end of the trestle, about 6 ft. back from the hole, or raise. Over these bins just under the car track, is a screen or grizzly, about 10 ft. long, with bars 1½ in. apart, set at an angle of about 35 deg. When the car is dumped, the waste rock slides over the grizzly. The larger pieces go over into the raise and the fine drops through the screen into the bin, where they become available for road material and concrete. When no rock is being drawn from the bin it simply fills up to the screen, and everything goes over into the mine. At one of our rock houses, where the old screen bars are still in use, and the crushers are set 12 ft. away from the screens, large feed pans or "tilting" pans have been installed, similar to those in use at some of the Calumet & Hecla rock houses. The pans are hinged at the crusher end, and extend from the crusher to the grizzly. At the screen end they are attached by means of a bail and chains to a large air lift, by which they are operated. On being raised they stand at an angle of about 38 deg. and feed the rock to the crushers.

The main storage bins at the older rock houses are of the rectangular pattern, with sloping bottoms. The rock is drawn from these bins by means of apron chutes, operated by long levers. Of late years most of the rock houses built are provided with large circular steel tank bins of great capacity. The loading chutes in these circular bins are set in the bottom directly over the center of the railroad track. They are an improved pattern closed by small doors, operated by a system of levers from one central point. These new style chutes are more easily operated than the old aprons, and will probably replace the latter at our older rock houses.

Let us now consider what has been gained by these changes: First, the large dump bin obviates the necessity of stopping the hoist in case of an ordinary delay at the crusher, such as the stopping of the crusher by a mass, etc. Second, we do away with screen bars and the expense of their up-keep. Under the old system Sunday repair work was a big item; since introducing the direct feed scheme, Sunday repair work has been almost entirely done away with. The sliding doors and chutes last from two and one-half to three years or longer, as do also the cradle gates at the crusher.

Perhaps the biggest saving, however, is in labor. Formerly a rock house crew consisted of six to eight men. At present two men will handle easily all that is hoisted.

Handling of mass copper and large boulders has been made comparatively easy by means of air lifts, trolleys and cranes, and whereas in olden times a rock house job was about the hardest around the mine, it has now become one of the easiest. Finally, to sum up the advantages in terms of actual saving in cost the comparison of rock house expense before and since remodelling is as follows:

Year.	Tons Crushed.	Labor.	Cost per ton Supplies, etc.	Total.
1906	671,785	$0.0629	$0.0342	$0.0971
1911	734,392	0.0262	0.0283	0.0545

Balancing Rock Crushers was the title of an interesting paper by **Mr. O. P. Hood, of** Pittsburgh. It is well known that heavy machines in which there is a vibratory motion, require specially rigid foundations in order that harmful vibration shall not be transmitted to the structure. Sometimes when several crushers are placed near each other the cumulative effect of their vibrations when the latter are in phase is very noticeable and is sometimes difficult to overcome.

The idea of balancing the moving parts of such machines so that the forces tending toward vibration would be counteracted, was the basis of Mr. Hood's paper. Some encouraging results have been obtained up to date, and the investigation is being continued. It was Mr. Hood's opinion that the principle of balancing such machines could be applied with resulting economy of power and efficiency of operation.

The following papers completed the program: "Some Applications of Concrete Underground," by H. T. Mercer, of Painesdale, Mich.; "Construction of Intakes at the Champion and Tri-Mountain Mills," by Edward Koepel, of Beacon Hill, Mich.; "The New Franklin Hoist," by R. H. Corbett; "Methods of Mining Iron Ore," by F. W. Sperr, of Houghton; "Development of Lake Superior Copper Mines," by F. W. Sperr; and some theoretical geological considerations, by Dr. L. L. Hubbard, of Houghton.

Election of Officers.

At the business meeting the secretary reported an enrollment of 486 members, and a cash balance in the treasury of $5.994. During the current session seventy applications for membership were received. The following officers were elected for 1913.

President—Pentecost Mitchell, Duluth, Minn.

Vice-presidents—F. J. West, Duluth, Minn., A. D. Edwards, Atlantic, Mich., W. P. Chinn, McKinley, Minn., to fill vacancy.

Managers—G. S. Barber, Bessemer, Mich., W. H. Johnston, Ishpeming, Mich., C. H. Baxter, Loretto, Mich.

Secretary—A. J. Yungbluth, Ishpeming, Mich.

Treasurer—E. M. Hopkins, Commonwealth, Wis.

The last act of the Institute was to pass resolutions on the death of Graham Pope, who was early associated with the Institute, and one of its ex-presidents.

The place of meeting next year has not been decided upon, but it probably will be in the iron country of Minnesota, in conformity to the usual practice.

Michigan College of Mines.

After the close of the Institute, the College of Mines acted as host to the visitors and threw open the laboratories for inspection. Small squads were guided by students to the different places of interest. Special demonstrations had been arranged in timber testing, petrography, wireless telegraphy and metallurgy.

Spelter is being produced this year at a greatly increased rate as compared with 1911. C. E. Siebenthal has compiled the figures for the first six months of 1912, and finds that if the same rate of production is continued during the last half of the year, the output of spelter will amount to about 330,000 tons, or 46,000 tons more than in 1911. Kansas, Illinois and Oklahoma are the principal spelter-producing states, ranking as named. The total capacity of zinc smelters reporting production at the beginning of this year was 81,582 retorts, to which it was contemplated to add 15,868 retorts in new construction. Allowing an annual average capacity of 4¼ tons per retort, the capacity of the 81,582 retorts for the first six months of 1912 would be 173,362 tons, less than 7000 tons in excess of actual production.

The Utah Copper Company's report for the second quarter of 1912 contains the following interesting data. The gross production of copper in concentrates was 9,457,346 lb., recovered from the treatment of 1,503,884 tons of ore containing 1.42 per cent copper. The average net cost of copper was 8.127 cents per lb. The Magna plant treated about 70 per cent and the Arthur plant 30 per cent of the tonnage. The latter has been remodeled, and its thirteen sections are ready for operation at this writing. Some improvements still remain to be made in the coarse crushing department, in order that full capacity may be maintained during the winter months, when the ores are more difficult to handle.

Cripple Creek supplied 56 per cent. of the total gold yield of Colorado in 1911, with an output of $10,562,653. Conditions in this district were much the same in 1911 as in 1910, for the subsidence of the water through the Roosevelt tunnel was so slow that it was not possible to materially increase operations.

Electrical Resistance of Sulphates.

BY A. A. SOMERVILLE.

Copper sulphate, $CuSO_4$, and iron sulphate, Fe_2SO_4, were the two compounds experimented upon.

Copper sulphate is the ordinary blue vitriol of commerce, commonly used in making what is known as the gravity cell for telegraphic use. When the crystals are heated so as to drive off the water they turn white. The iron sulphate crystals

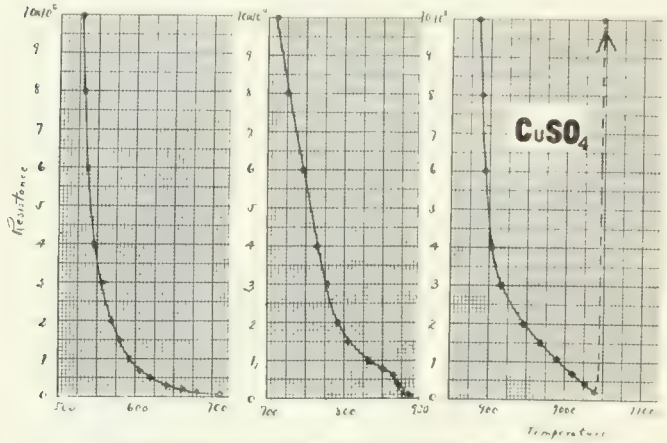

FIG. 1.—CHANGE OF RESISTANCE OF POWDERED $CuSO_4$ WITH TEMPERATURE.

are white but tinged with a yellowish brown color. When heated they do not change color until a new compound is formed.

In each case the crystals were pulverized and the powder placed in a porcelain tube that could be heated. Terminals were placed in the ends of the tube so that the electrical resistance of the sulphate could be measured. The heating was done in an electrical furnace and the resistance measured with a resistance thermometer connected to an automatic recorder.

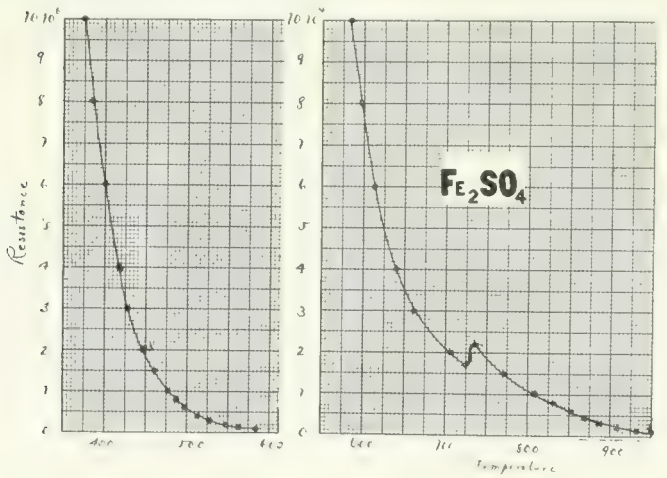

FIG. 2.—CHANGE OF RESISTANCE OF POWDERED Fe_2SO_4 WITH TEMPERATURE.

At about 865 degrees Centigrade, the copper sulphate begins to slowly and gradually decompose, forming $CuO + SO_3$, black copper oxide and sulphur trioxide. The sulphur trioxide is driven off at this temperature, leaving the black copper oxide in small quantity.

The electrical resistance of the copper sulphate is infinite at room temperature. The powder was contained in a tube one centimeter in diameter and three centimeters long. It measured 10,000,000 ohms at about 525 degrees. The resistance decreases in a regular manner until about 860 degrees is reached. Here the rate of change of resistance is altered due to the decomposition beginning. As the sulphur trioxide is driven off, leaving a smaller volume of copper oxide than before, the resistance decreases relatively fast. At about 1050 degrees the cross-section of material left is so small that the electrical circuit was broken as indicated by the apparent infinite resistance again.

The iron sulphate decomposed quickly and suddenly at about 730 degrees Centigrade, forming $Fe_2O_3 + SO_3$, iron oxide and sulphur trioxide, drawing oxygen from the air to complete the transformation.

The iron sulphate measures 10,000,000 ohms at about 375 degrees. Its resistance decreases similarly to that of the copper sulphate. At about 730 degrees there is a sudden decomposition and the sulphur trioxide is all driven off in a short time, making an abrupt break in the temperature-resistance curve. From there on the resistance is the same as for iron oxide.

The points where decomposition begins are very definitely shown on the temperature-resistance curves.

An Electric Still.

In the accompanying illustration, Fig. 1, is shown an electric still adapted for difficult distillations, which was described in our Congress issue, page 606, but not illustrated there. The still was devised by **Mr. Irving C. Allen,** of the U. S. Bureau of Mines, Pittsburgh, who described it before the section on organic chemistry during the sessions of the Congress.

Turn from a block of wood a model the size and form of the distilling flask, with the bulb and neck in one piece, and saw the model into halves from top to bottom. Hollow out the bulb and neck to form a shallow dipper making the cavity about 1 cm. deep, and leaving the rim about 3 mm. thick. Drill holes the size of a small wire brad 1 cm. apart and 3 mm. below the edge of the rim of the dipper and along the handle or neck as far as it is desired to have the heating wire. Insert brads through these holes from the inside and allow the points to project about 3 mm. thus forming a comb of brad points around the outside of the dipper near the edge, Fig. 1, a.

Then, after greasing well the convex surface of the mold to prevent the paste from sticking, wrap the heating wire back and forth, the wires being 1 cm. distant from one another, across

FIG. 1.—ELECTRIC HEATER AND MOLD.

the convex surface of the dipper between these points, in the manner shown in Fig. 1, a, tying the wire in place with asbestos cord and making its two ends fast to binding posts projecting at convenient positions. Lay the wired form, convex side up, on a smooth board covered with a sheet of paper and apply freshly prepared paste to the desired thickness, about 2 cm.

Allow the paste to harden over night. Remove the brads from the inside of the mold. The heater will then be released and ready for the final drying described above. Do not pass a current through the wire until the heater has been thoroughly dried, else rapid corrosion of the wire will result.

Final Meetings of the Eighth International Congress of Applied Chemistry.

In our extra issue of September 12 a full report of the proceedings of the Congress up to the night of Wednesday, September 11th, was given. After this date there were only the final sessions of the Sections of Thursday, September 12, the banquet on the evening of the same day, and the closing business meeting on Friday, September 13.

The banquet at the Waldorf-Astoria, on Thursday evening, was the great social function of the Congress.

The grand banquet was attended by over 1000 men and women members of the congress and was the occasion of many expressions of felicitation by visitors from foreign lands. On behalf of our own country there were addresses by representative public men.

Dr. William H. Nichols, president of the congress, presided at the banquet. In the absence of Governor Dix the State of New York was represented by Dr. John H. Finley, president of the College of the City of New York, who spoke to the evident delight of his audience.

Mayor Gaynor's Address at the Banquet

The principal speaker of the evening was Mayor Gaynor, of New York City, who was the guest of the chemists. In introducing Mayor Gaynor Dr. Nichols spoke of him as "the man who has the hardest job in the world." Below we give the text of the Mayor's address:

"As I heard the gentleman call off the announcements in five languages, I could not help wondering all the while whether there were not possibly seven or eight languages in which he could keep silence. Or maybe he could keep silence in all of them, which is better yet. I knew my job was a difficult one without the chairman announcing that to this audience. I think it is pretty well known, and I also know possibly that the harder you work in it to do right the less thanks and the more abuse you get from some quarters here in the City of New York. But the quarters, after all, are quarters that do not count for much.

"I desire to make an apology to you. If this Congress had been held in any of the cities throughout the country from 20,000 and upward the newspapers of those cities of 20,000 and upward would have devoted more space to your proceedings than the newspapers of this city have done. I cannot refrain as Mayor of the city from making to you an apology on that score, for the like of it I do not think you have ever seen before, and I am sure you will not encounter it in St. Petersburg next year. Still it is very natural. The papers here of large circulation, who make daily affidavits, each of them, that its circulation is the largest in the whole world, dole out their ideas in types from an inch to 6 in. long. And not being content with black type even of that length, some of them, as you must have noticed, Sir William, and the rest of you, have to use red ink.

"They think our skulls are so thick that there is no other way of penetrating them, even with the commonplace thoughts which they seek to convey. But I may say to you that these papers speak principally to the underworld of this town, the great underworld of 200,000 in this great city of 5,000,000, and that underworld are not scientists, I assure you. And it needs big type, and red type, to penetrate their skulls, and some of them have skulls so thick that possibly you could not get anything into their heads, except in the—I don't know whether I ought to say this—except in the same way that you get a joke into a Scotchman's head—that is to say, by taking out a section of his skull and poking it in.

"You men are the forerunners of human thought and of progress throughout the world. You make the world move forward. You are in the very front. You have revolutionized things throughout the world, and yet, may I say to you, that with all you have done we are still only on the edge of things. Isn't that so? We are only beginning. And yet you are working, experimenting, bringing out new processes and ways of applying them. The manufacturers of the world are now making fortunes out of things which a few years ago they threw into the waste heap, all through the science which you have developed. I hope you get your share of it.

"And yet, as I sat and looked at you to-night and saw how well and prosperous and well paid you all looked, I said to myself, what condition will they all be in when the impending state of socialism comes into reign, and a great many people think it is now to come to pass very soon. The Socialists have not yet determined whether they shall pay every man according to his necessities, every worker according to his necessities, or according to his productive capacity, whether mental or physical, or both. If they determine to pay only according to your necessities, that is to say, to each just enough to make him live, you people will have to come down a peg or two under socialism. And I am afraid you won't work so mighty hard any more. I am afraid the development in chemistry will come to quite a standstill when that comes to pass; and that will be true in all the sciences, and in all departments of human endeavor, and in all the arts. When everybody is paid alike I think we will all try to live alike and do as little as we can."

Mrs. Baekeland on the Advancement of Women.

The unique place of honor among the list of speakers was awarded to Mrs. Leo H. Baekeland, who was the only woman to address the Congress. Mrs. Baekeland acted as chairman of the Congress ladies' committee and contributed greatly to the success of the meetings in Washington and New York by arranging for the entertainment of the ladies.

In her brilliant and dignified address at the banquet she took for her subject "The Advancement of Women," speaking as follows:

"Mr. President, Ladies and Gentlemen:

"I am not a real chemist. I am only a chemist by birth, by marriage, by friendship; and so, it is as a woman that I will speak to you to-night, as a woman and as a friend.

"It has often been my good fortune to be amongst you; and I have derived so much strength from the atmosphere of intelligence and broad-mindedness which prevails at all your meetings, that I think it is greatly due to this influence that I have become what is called a new woman.

"Some time ago this would have been a confession; to-day it is a declaration of faith. Some time ago the new woman was the butt of all the stale jokes; to-day she is the deep concern of all thinking men.

"Do not imagine that all the new women want to break windows; I know some very charming ones who are only breaking hearts. I know some very fine ones who are trying to mend hearts.

"If man or woman, if any human being could have the mental ability of man—and at the same time the charm and tenderness and love of woman, this being would at once take a great step towards human perfection. Such a step is not at all impossible now, and such women should exist and do exist—women of the type of Jane Addams, who works with the directness and power of man and with the devotion and love of woman.

"Do not be frightened by the cry of equality, by the cry of

rights for women; it is the cry of a dignified being, asking for a dignified place in society. Not the place of a toy, not the place of a pet, not the place of a spoiled and capricious child as so many of us unfortunately are, but the place of a dignified being.

"We know that we have much to learn, but we are willing and ready to do so; and when we see a gathering like this one, where hundreds of ladies have come from all parts of the world to join a Congress of Chemists, we know that 600 ladies have had a chance to improve and to grow.

"It is to your generosity, gentlemen, to your cordiality, that we owe these few delightful days of education, of good fellowship, of advancement and in the names of all the ladies present I thank you."

Addresses by Delegates.

A large number of representatives of foreign countries spoke briefly on the value of the international congress and the success of this meeting. The following list of speakers shows the world-wide nature of the gathering.

William Percy Wilkinson, representing Australia; Rudolph Wegscheider, of Austria; B. Setlik, of Bohemia; Paul Hagamans, Consul General of Belgium at Philadelphia; Anthony McGill, of Canada; Belisario Diaz-Ossa, of Chili; Yung Kwai, of China; Don Guillermo Wiles, of Colombia; Einar Biilmann, of Denmark; Leon Lindet, of France; von Buchka, of Germany; Rudolph Hofmann, of Prussia; Gilbert T. Morgan, of England; Giuseppi Bruni, of Italy; Adolfo P. Castanares, of Mexico; Alfred Sinding-Larson, of Norway; Mirza Ali Kuli Kahn, of Persia; Paul Walden, of Russia; Knut Wilhelm Palmaer, of Sweden; E. P. Treadwell, of Switzerland; James Moir, of the Union of South Africa; Edward Robinson, director of the Metropolitan Museum of Arts and Sciences; Edmund Otis Hovey, American Museum of Natural History of New York; President Arthur Little, of the American Chemical Society; Dr. Strohmer, of the International Commission of the International Congresses of Applied Chemistry, and Sir William Ramsey, of the International Commission of International Congresses of Applied Chemistry.

Ninth Congress to Be Held in St. Petersburg.

The last acts of the eighth congress were to determine the place of holding the next meeting and to take action on the resolutions which had passed the several sections. The ninth congress will be held in St. Petersburg in 1915. The president-elect is Dr. Paul F. Walden, professor in the Riga Polytechnic High School. The honorary president of the ninth congress is Prof. Demetrius P. Konowaloff, of the University of St. Petersburg.

This was decided in the final business meeting held on Friday morning in the Great Hall of the College of the City of New York. This final meeting was also devoted to the consideration of resolutions.

Action on Resolutions.

The proposal to adopt Esperanto as one of the official languages for the ninth congress met with opposition on the part of the International Commission, and was rejected on the ground that it would be more appropriate for the next congress to pass on the matter as it could then be considered by a more representative cosmopolitan body.

An atomic weight table for commercial purposes, to be issued every five years and considered as a standard, had been proposed by the section of Analytical Chemistry. This was modified by substituting the official table of atomic weights now issued by the International Commission, adopting the table of 1912 as a commercial standard until the next congress meets in 1915.

A recommendation was adopted that at this congress and future congresses the reports of the International Commission of Analyses and of the other commissions appointed by the congress be printed in the transactions and an appropriation of $200 was made for this work.

A resolution directing the congress to investigate tests for hydrometers and other instruments, and to prepare tables on the density and expansion of solutions and fluids, was rejected.

Official notice was taken of the work of the committee on the stability of explosives, and it was recommended that a permanent committee of European experts be appointed to bring the committee's regulations to the attention of their respective governments and urge their adoption. The report of the committee will be printed in full and issued to the members of the congress.

Action was taken toward the appointment of a committee to confer with the International Hygiene Congress, to determine simple bacterial tests to control disinfectants.

The International Committee on Analytical Methods for Food Products was continued and an appropriation of $200 was allowed for its work.

The sub-committee on organic coloring matter in foods was continued, with instructions to suggest to all governments that they adopt identical regulations with regard to the use of these substances, and to endeavor to secure the co-operation of manufacturers in preparing a report on the reactions and analysis of organic coloring matters.

The congress took negative action on a proposal "to examine and report upon the progress and position of chemical industry in each of the countries represented at the preceding congresses, having particular regard to the relation between the development in the different branches of chemical industry and custom tariffs."

The work of the International Commission on Annual Tables of Constants received the moral support of the congress to the end that financial support might be obtained from scientific societies and institutions.

The committee appointed to prepare resolutions of thanks to societies, institutions and individuals for their support of the eighth congress presented its report, which was adopted. Following this, Dr. Carl Duisberg spoke appreciatively of the work of the president of the congress, Dr. W. H. Nichols, and asked that a vote of thanks be expressed to him for his services. This was done by a rising vote.

In conclusion, representatives of Belgium and Japan, who had not had an opportunity to speak at the banquet, made short addresses. President Nichols then declared the congress closed.

Additional Abstracts of Congress Papers

Section on Electrochemistry.

Ductile Tungsten.—In the last few lines of Dr. **C. G. Fink's** paper on page 581 of our issue of September 12, the table of properties contains a number of slight typographical errors. The corrected values are:

Young's Modulus of Elasticity: 42,200 kg. per sq. mm. (steel 20,000).

Melting Point: 3177 deg. (Langmuir); 3100 deg. ± 60 deg. (Pirani & Meyer).

Magnetic Susceptibility: $+0.33 \times 10^{-6}$ (Honda) i.e., practically non-magnetic.

Insoluble in HCl, H_2SO_4, HNO_3, HF, NaOH, KOH (aq), and mixtures of $K_2Cr_2O_7 + H_2SO_4$, soluble in mixtures of HF and HNO_3 and in fused nitrates and peroxides.

Electro-Analysis with Acidified Chloride Electrolytes.—In a paper on the electro-analysis of copper, antimony, bismuth and tin with acidified chloride electrolytes, by **Eugene P. Schoch** and **Denton J. Brown**, of the University of Texas, Austin, Tex., it is pointed out that solutions of chlorides of metals acidified with hydrochloric acid heretofore have been considered to be unsuitable for the electro-analytical deposition of metals, probably on account of the oxidizing effect of the liberated chlorine.

Since the liberation of chlorine can be prevented by the ad-

dition of a reducing agent, and since such electrolytes present all the advantages of simple acid electrolytes desirable for electro-analytical work, while in many respects they are more serviceable or convenient than either the "nitric acid" or the "sulphuric acid" electrolytes advocated by Foerster and by Sand, the authors decided to investigate their use, particularly with metals such as copper, antimony, bismuth and tin for which hydrochloric acid electrolytes are generally considered to be unsuitable and for two of which—namely, antimony and tin—the use of any simple acid electrolyte cannot be said to have been made practicable even by the recent excellent work of Sand.

The authors found that copper, antimony, bismuth, and tin may be deposited quantitatively and in good form from "hydrochloric acid" electrolytes if suitable reducing agents (formalin, hydroxylamine hydrochloride, oxalic acid, etc.) are added to them. By these means the authors have also found it possible to separate copper from tin and determine both from the same sample of electrolyte, thus reducing the otherwise troublesome analysis of bronze to a very simple operation; and they have found that metals with a potential "more zincic" than that of tin do not interfere with the determination of copper by this method.

The essential fact that makes this electrolyte serviceable is the presence of the reducing agent. Very probably the deposition of the metal takes place by the discharge of the "lower valence" ions, and the reducing agent serves, in effect, to change the "higher valence" ions to the "lower valence" ions.

These methods present many advantages over older methods. The electrolytes are easily prepared, because all of the metals are soluble in aqua regia, and all of their compounds are soluble either in this reagent or in hydrochloric acid. These electrolytes are free from odor as compared with the sulphide electrolytes frequently used for antimony and tin. The results indicate that the deposits obtained are probably free from inclusions; and the time required for the determinations characterizes these methods as "rapid" methods.

Details are given of the electrolytic apparatus employed, the determination of tin, the determination of copper, and its separation from other metals, the determination of antimony, and the determination of bismuth.

Inorganic Addition Agents for Deposition of Copper.—In a paper on the function of inorganic addition agents in the electrolytic deposition of copper by **Elwood B. Spear**, of the Massachusetts Institute of Technology, Boston, Mass., the theory is advanced that the function of inorganic addition agents in the electrolysis of copper solutions is to keep the copper in solution. The fundamental assumptions are: That some particles of copper may assume the colloidal form at the moment of giving up their electric charges at the cathode. That oxidation may take place on the cathode during the passage of the current.

Experimental proof is given to show that copper is continuously dissolved and reprecipitated at the cathode during the electrolysis of copper solutions.

The theory explains the fact that good deposits of copper become bad if the electrolysis is continued too long.

Carbon in Electrolytic Copper.—A paper by **Ellwood B. Spear, C. Chow** and **A. L. Chesley** shows that it is possible to precipitate carbon at the cathode during the electrolysis of a copper sulphate solution containing a little nitric acid and a small amount of gelatin.

Evidence is given to indicate that at least some of the carbon is in a free state in the deposit.

It is concluded from the experiments that an oxidizing action must have taken place at the cathode. This oxidation is probably due to secondary reactions.

Dry Cells.—A paper by **Carl Hambuechen** and **O. E. Ruhoff**, of Madison, Wis., gives some physical and chemical data on several typical American brands of dry cells, and on the materials used in their manufacture.

The chemical tests upon materials are made both for useless but inert impurities, and for actively injurious ones.

An important physical characteristic of raw materials used in battery manufacture, and of battery mixtures, is the electrical conductivity. The method of determining this is described and data are given upon various materials and mixtures. Conductivities depend upon the chemical composition of the materials or mixtures and upon the size and composition.

Tables are given showing dimensions and weights for several typical brands of cells which were investigated, and the chemical composition as regards the principal ingredients, namely, carbon and graphite, manganese dioxide, zinc chloride, ammonium chloride and water.

Carborundum.—In a paper on the study of a small carborundum furnace by **Wilder D. Bancroft, L. V. Walker,** and **C. F. Miller** of Cornell University, the authors give the results of tests in which they have studied the yields in a 30-kw and a 20-kw experimental furnace, as affected by length of run. A granular carbon core was used for the series of experiments. With the 30-kw furnace tests were made lasting 2, 2.5, 3, 3.5, 4, 4.5, 6 and 8 hours respectively. With the 20-kw furnace tests were made lasting 2.5, 3.5, 6, 10 and 14 hours respectively. Curves are given for core temperatures during a run, and for temperatures in one other part of the furnace. Curves are also given for yields of graphite, carborundum and siloxicon for different lengths of run. The results for the 20-kw furnace are given in Fig. 1.

The formation of graphite appears to follow approximately a straight line curve for some time, and then starts to bend at about the same time that the carborundum formation has reached its limit. The siloxicon curves show a slight bend in the opposite direction, at this same point. It is almost self-evident that this would be the case, owing to the fact that the carborundum layer has arrived at a maximum radiation surface as well as at a maximum temperature and hence it is most efficient in heating the siloxicon and unchanged charge about it. The slight decrease in the rate of formation of graphite is hard to explain except by the stationary stage theory, as there is always a layer of carborundum which could furnish carbon on decomposing, also an excess of carbon in the core itself. It may be that the carbon in the core is not as available owing to the size of the granules.

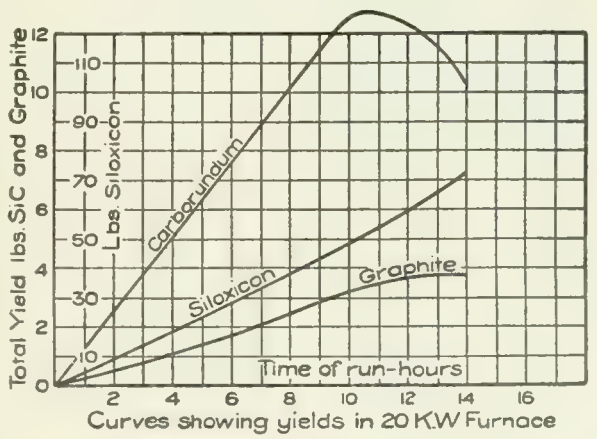

FIG. 1.—YIELD CURVES OF CARBORUNDUM FURNACE.

The carborundum curve shows a flat maximum, indicating that at this point the heat given off by the SiC is equal to the calories received from the graphite and core, none of the energy being expended to raise the temperature of the SiC layer. This is the beginning of the stationary stage. In the 30-kw furnace this maximum point is reached in six hours of run; in the 20-kw furnace at the end of 10 hours. The 14-hour run on the 20-kw furnace shows that the conditions for a stationary stage are by no means permanent in the carborundum furnace, and that there is such a thing as a rapid decomposition of SiC if

the run be continued too long. This could be explained as due to the heat-insulating effect of the then rapidly increasing siloxicon yield which would confine more heat in the SiC zone, causing the SiC to decompose at an increased rate.

Large Electric Furnaces.—A paper in German by **Dr. Rudolf Taussig,** of Vienna, Austria, gives a review of the "present status of the development of large electric furnaces" with especial reference to the Helfenstein patents, which have been repeatedly noticed in this journal. The furnaces are particularly intended for the manufacture of calcium carbide and ferrosilicon. One 10,000-hp Helfenstein furnace has been in operation for several months in France and is working satisfactorily. Other large furnaces are in course of erection.

In increasing the size of the electric furnace the difficulty

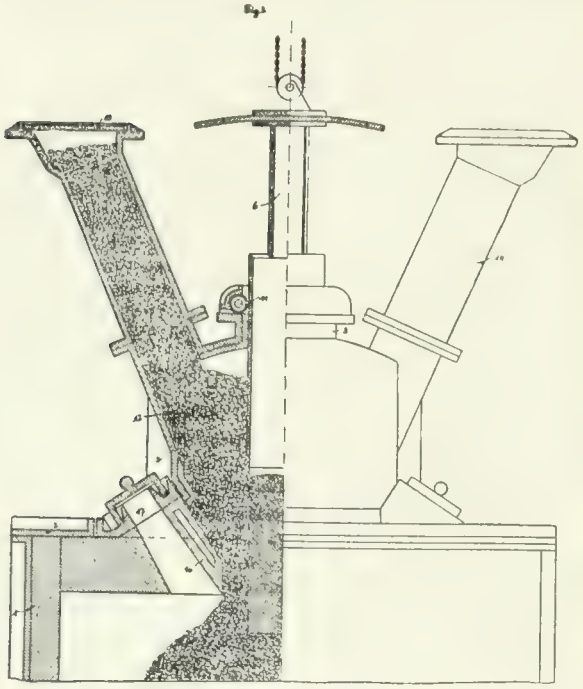

FIG. 2.—TOP OF LARGE ELECTRIC FURNACE.

was experienced that the arches of the roof would not stand the high temperature for a great length of time. This difficulty can be overcome by constructing a furnace of several shafts side by side, each with its own vertical top electrode, but all of them being connected together electrically by bottom electrodes in form of a conducting bottom common to all the shafts. Besides the electric connection there is no other connection between the shafts so that it is possible to produce different products simultaneously in the different shafts.

A second important improvement was made in closing the furnace airtight. The difficulty was in the method of feeding the charge and the way in which the upper electrode is suspended. Fig. 2 shows how this problem is solved by Helfenstein. Fig. 3 shows a 12,000-hp ferrosilicon furnace.

The increase in size has reduced considerably the cost of manufacturing. While with the smaller furnaces the price of calcium carbide was 18 to 20 kr. (1 krone = 20 cents), this was reduced by increasing the size of the furnace to 15 or 16 kr. and a further reduction to 12 or 13 kr. was obtained by using an airtight furnace.

The cost of making 50 per cent ferrosilicon was reduced by 20 kr. per ton by closing the furnaces airtight

The large closed furnaces are economical on account of their simplicity of the operation, the saving of electrode material and reduction in wages, and the smaller investment per ton of output. Also on account of the much lower maintenance cost. These large furnaces are operating for years without reserve, since only the electrodes and the roof are used up. The replacing of the electrodes is very simple and the repairs of the roof can be made during operation.

While Helfenstein's furnaces were formerly used chiefly for calcium carbide and ferrosilicon, he is paying attention now also to other electric furnace problems, for instance, for reduction of iron ores and steel refining. The Stora Kopparbergs Aktiebolag in Falun are erecting a Helfenstein furnace for iron ore reduction. A Helfenstein furnace with six shafts has a capacity of 24,000 hp and can produce 250 tons of pig iron per day.

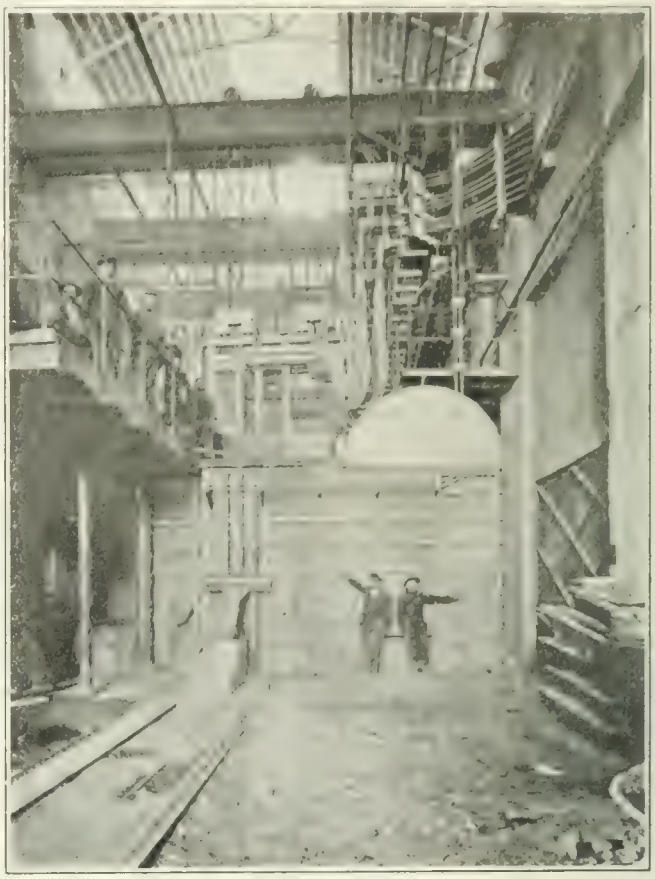

FIG. 3.—12,000-HP FERROSILICON FURNACE.

Electrical Precipitation of Suspended Particles.

One of the interesting papers presented before the section on electrochemistry was read by **Mr. Linn Bradley,** engineer of the Research Corporation, who gave a brief review of the processes of condensing dust and fume by means of high-tension electric currents. These processes are the invention of Dr. F. G. Cottrell, who has turned over his patent rights to the Research Corporation to be administered in the interests of the Smithsonian Institution. The Cottrell processes have been described in this journal, March, 1912, page 172, and May, 1912, page 313. Mr. Bradley's paper dealt only with the various applications of the process, one of which, in the cement industry, was described in our special Congress issue, page 611.

The problem of removing suspended particles from gases becomes a serious one when the volume of gases is very large, or the temperatures high, or the gases contain materials which exert a corrosive action upon flues, chambers and apparatus.

The variety of problems and conditions is very large, but they may be divided into three general classes, as follows:

1. Where the composition of the gases is such that they

are the cause of complaint on the ground of nuisance and damage to property.

2. Where the values contained in the gases render their recovery quite necessary on the ground of economy, but where the gases do not constitute a nuisance.

3. Where the gases may be considered sufficient cause for complaint, and yet contain values which should be recovered.

PRECIPITATION OF SMOKE AND CINDERS.

In the first class, and as a further illustration of the growing range of application of these processes, may be mentioned the black smoke, ashes and cinders coming from the stacks of some of the large power plants where the boilers are being forced. In some of these plants the operating departments have endeavored in various ways to purify their gases, so as to avoid any complaints. In a small plant, with proper arrangement of boilers, arches, settings and flues, the stack gases seldom give rise to complaint. Undoubtedly the proper method of attacking this problem is to endeavor to obtain proper combustion. However, there are a great many instances where complete combustion is not desired, and in such cases these processes may prove to be of value in overcoming the nuisance due to black smoke or other suspended particles.

Among its other activities the Research Corporation is at present engaged in demonstrating the removal of such suspended particles by the electrical precipitation processes at one of the largest power plants in the City of New York. In this plant there are nearly one hundred boilers, connected to four smokestacks approximately 300 ft. high by 22 ft. in diameter. The average velocity of the gases through these stacks is estimated at 38 linear feet per second. During the evening, when the peak-load is on the station, it is necessary to force the boilers, so that they are delivering perhaps 100 to 150 per cent in excess of their rated capacity. Automatic stokers are used, but even with the greatest care considerable ashes and cinders are caught up by the draft and carried toward the stacks. The cross flues have been enlarged, in order to reduce the velocity of the gases; but, although some of the heavier particles are deposited in these chambers, the exit gases carry a fairly large amount of cinders and ashes.

Experiments upon this particular material indicate that the greater portion of the large particles can be caught if the velocity in the flue is reduced sufficiently and ample time is allowed for the particles to settle out of the draft by gravity; but flues large enough to produce this result would be prohibitive. Some particles are so light that a slight movement of the gas easily keeps them in suspension. If we endeavor to increase their weight by water sprays or similar means, we interfere with the draft, and may not find our efforts successful, because some particles resist moisture and are extremely difficult to remove by this method. If we are able to construct an apparatus which will not be prohibitive in size, and does not seriously interfere with the draft, whereby we can overcome the buoyancy of the particle in the gas and remove it from the influence of the draft, we will succeed in cleaning the gas of the suspended particles.

The actual net amount of energy necessary to withdraw these particles from the moving gas is very small indeed. The problem is to design and construct such an apparatus, then to place the electrical charge upon the particle and introduce sufficient energy to compel the particle to migrate to some point away from the rapidly moving gas. This may be accomplished by the use of high-tension direct current, either intermittent or continuous. Discharge electrodes and collecting electrodes are placed in a chamber and the gas containing the particles passed between them. The gas is ionized and some of the ions collect upon the particles, thereby charging them electrically. Inasmuch as the charged particles are within a strong electric field of constant polarity, they are driven to the collecting electrodes.

The construction of these electrodes may be varied considerably, to suit the special conditions of each particular problem. In most instances the collecting electrodes are grounded, and to meet different conditions various forms of electrodes are used. The voltages used range from 15,000 up to as high as 50,000 or more, depending upon the size of installation and conditions of the gases to be treated. It will be realized that it is desirable to operate on gases at a high velocity and during a short period of time, in order that the installation may be made as small as possible. Results at present in hand indicate the feasibility of removing the cinders, ashes and black smoke from these power house gases at a reasonably high velocity and without any serious interference with the draft.

Much more might be said about this problem, but it may be more to the point, in this general survey, to mention some phases of the work bearing upon other industries.

APPLICATION IN SMELTING ELECTROLYTIC SLIME.

Shortly after the organization of the Research Corporation, last February, investigations were undertaken on the gases arising from the smelting of the slimes obtained in electrolytic copper refining. The copper, as received at the electrolytic refinery, generally contains some gold, silver and other precious metals, as well as arsenic, selenium, tellurium and many other elements in small quantities. During the purification of the copper by electrolysis most of these impurities settle out from the electrolyte. This sediment, called electrolytic slime, is then treated in another department, primarily for the recovery of the gold and silver.

It is common practice in some refineries to dry this slime and then give it a furnace treatment. The volatile elements are driven off in the gaseous state and subsequently condensed in the flues. During the furnace treatment considerable silver is vaporized, some of which condenses quite near the furnace exit. At this point in the flue dust may be found, assaying very high in silver. Considerable gold may also be found at this point, probably having been carried over mechanically. Further along the flue arsenic, antimony, selenium and other elements, or their compounds, condense, thus forming a thick chemical fume.

It is interesting to note the tendencies of the various compounds to deposit. For instance, some of the silver compounds or metallic particles are very light and finely divided, and it is extremely difficult to effect a satisfactory recovery by settling chambers, centrifugal dust apparatus or by water sprays and scrubbers. Gold has been found a long distance from the furnaces, but as a rule it is the first to deposit. The influence of one or several volatile metals upon the volatility of other metals, especially at various temperatures, has not been studied very extensively, but most authorities state that the loss of silver is increased in the presence of lead or zinc. Probably arsenic or antimony also exert an influence upon silver. It would be interesting and of considerable value to be able to consult curves of vapor tensions of these various elements under the varying conditions of these refinery gases.

Samples of this kind of dust from various refineries show it to have a range of at least from 100 to 2,000 ounces of silver per ton. The gold content is not apt to vary so greatly. Fume has been collected after passing through water scrubbers (so arranged that the gas was saturated and carried water particles in suspension) and found still to contain large amounts of precious metals. The character of the fume will depend, of course, upon the composition of the copper received at the refinery, as well as upon the operations of the refining furnaces. It is almost impossible

to filter this gas, because of its corrosive action upon the filtering medium and its tendency to clog the same. Results obtained upon these gases lead to the conclusion that practically all of the values can be readily recovered by the electrical precipitation processes, thereby insuring a greater net profit in these departments.

The problem of recovering the values from the dust collected is receiving considerable attention. If all the collected dust is fed back into the furnace the highly volatile elements will again be driven off, subsequently condensed, and, in turn, collected. This will permit the impurities to concentrate and increase to such a point as to be objectionable. Experiments are now being conducted with a view to facilitating the recovery of the precious metals in a pure state from this precipitated fume. The proposed method may open up an opportunity for improvements in the present practice of treating these electrolytic slimes.

CONDENSATION OF ACID MIST.

The electrical precipitation processes have been in steady use for the collection of sulphuric acid mist from parting kettles, in one silver refinery for a number of years, and have given excellent results. Another application recently developed is the equipment of acid concentration stills, so as to recover the small amount of sulphuric acid being carried away by the gas. The installation is very compact, the power consumption small, and very little attention is required. For installations of this character special devices for overcoming insulation difficulties and promoting the ionization by the discharge have had to be worked out. The pubescent electrodes are one of the most important features in installations of this type.

PRECIPITATION OF SMELTER FUMES.

One of the large lead smelters in the western portion of the United States is installing the processes on its roaster stack. Godfrey machines and Dwight-Lloyd sintering machines are employed, delivering their gases to a common flue. This flue has a cross-section of such size that the average velocity of the gases is about 500 lin. ft. per minute. A large amount of the very heavy particles is deposited in the first 200 ft. of flue, but the fume is being discharged from the stack after having traveled a much greater distance.

Preliminary tests were made on these gases at a point about 150 ft. from the stack base. The temperatures varied from 100 deg. C. to 150 deg. C. During these preliminary tests the ore charges upon the sintering machines were varied and checked against the assays of the dust recovered electrically, during the day, in order to ascertain how the different charges influenced the loss of lead. Assays of recovered dust varied from 20 per cent to 45 per cent lead during this period. Even at this distance from the roasters considerable silver and an appreciable amount of gold was found in each sample. The dust recovered was dry and could be handled easily, as it was so dense and compact that a little draft did not blow it away.

The smelter is now proceeding with an installation on a larger scale and it is expected that considerable values will be recovered. Furthermore, this installation may make it possible to push the roaster department to a greater tonnage, due to the ability to collect any materials carried in suspension by the gases. In some roasters, a fairly large percentage of sulphur trioxide is produced. Apparatus can easily be designed to handle this character of gas successfuly, without undue deterioration.

PURIFICATION OF ILLUMINATING GAS.

Another recent application of these processes is in the removal of tar and suspended carbon from illuminating gas. Mr. Walter A. Schmidt has directed the work upon the gas manufactured from crude petroleum at one of the gas plants near San Francisco. A complete clearance of all visible particles was obtained. In the eastern part of the United States the work of Prof. A. H. White, of the University of Michigan, should be mentioned. Under the auspices of the Michigan Gas Association, Prof. White has conducted extensive investigations, primarily upon the removal of tar from gas manufactured from soft coal. The results were so gratifying that negotiations have been instituted for a larger installation for this purpose. The tar is collected upon the collecting electrodes and runs off into sealed chambers. This field promises to be a very wide one.

Several months ago, prior to the organization of the Research Corporation, Dr. F. G. Cottrell made arrangements with Prof. R. K. Duncan, of the University of Pittsburgh, where the latter arranged to use the Cottrell processes for conducting investigations upon the smoke problem of the city of Pittsburgh. Dr. Strong, Dr. Benner and others have been of assistance in this important problem.

Many other problems of a similar nature to some of those mentioned above have been brought before us and an effort will be made to adapt the processes to them at the earliest possible date. There are many places adjacent to New York City wherein considerable values may be recovered, and at the same time improve the atmosphere, at least in so far as suspended particles and obnoxious fumes are concerned.

Subsequent to the reading of the paper, Mr. Bradley explained in detail the construction of the small apparatus prepared for demonstrating the Cottrell processes. The first test was upon the precipitation of cement dust, which was blown through a pipe 6 inches in diameter. The effect of the high tension current was to collect all of the dust within the pipe. The cement dust was shipped from the plant of the Riverside Portland Cement Co., at Riverside, Cal., having been collected by the Cottrell processes at that plant. The dust was placed in a bottle and compressed air introduced in such a manner as to pick up and distribute the dust within it. A test was next made upon some chemical fumes. Compressed air was blown through bottles containing concentrated ammonia and concentrated hydrochloric acid, separately, and the chemically laden gases mixed in a chamber just prior to being introduced into the electric treater. Dense fumes of ammonium chloride were thus obtained and the effect of turning the current on and off was demonstrated. A further and last test was upon tobacco smoke.

Section on Metallurgy and Mining.

Sampling and Assaying of Silver Ores Containing Cobalt, Nickel and Arsenic.

The ores found in the Cobalt, Ontario (Canada), mining district are arsenides of cobalt, nickel and silver. They contain also native silver, and on account of their complex nature are difficult to sample and assay with accuracy. Consequently, various local methods have been adopted. This paper by **James Otis Handy,** of Pittsburgh, Pa., describes the practice of hand sampling at the Pennsylvania Smelting Company, Carnegie, Pa., and the methods of control assay used in the Pittsburgh Testing Laboratory.

Sampling.—Low grade ore is shipped in bulk, and high grade ore and concentrate in sacks and barrels. The moisture sample is taken when the cars are unloaded or when the sacks and barrels are opened. For low-grade ore the sample consists of four separate portions of 6 lb. each, taken at intervals during unloading. With the high grade the sample is selected from different parts of the pile after it is thoroughly shoveled over.

The principle of the methods of sampling adopted is that of

successive selections of a portion of the ore, with intermediate grinding of the selected portion. Low-grade ore is first crushed to 1½ in. and divided by shoveling two parts to the storage bin and one part to the sampling floor. The floor pile is then divided by shoveling one to bin and one to sample. The latter is now one-sixth of the whole lot and should not weigh less than 6000 lb. This is crushed to ½ in. and quartered to 1700 lb.

The ore is crushed again till all passes the ¼-in. screen, then turned and shoveled over at least twice. It is then quartered down to not less than 300 lb. which is crushed by rolls to pass a 10-mesh screen, then turned and mixed thoroughly and quartered to not less than 60 lb. This sample is ground in a mill to pass 20 mesh and is cut down by a Jones sampler to about 4000 grams, which is ground in a pebble mill till the ore (except metallics) all passes a 120-mesh sieve. Each part of the final sample consists of "pulp" and "metallics" weighing together about 1000 grams per sample. Four sets are made. If the total amount of "metallics" from the 4000 grams is not over 3 grams, it is jointly assayed by the assayers representing buyer and seller. The "metallics" are scorified with test lead and borax glass and the button is cupelled. The weight of the silver bead is then recorded on each sample envelope with the weights of moisture, pulp and "metallics." If the "metallics" exceed 3 grams they are divided into two or more parts, to accompany the pulp samples.

High Grade Ore.—Under this head is included all ore containing over 500 oz. of silver per ton or ore 300-500 oz. containing its metallics in coarse form and unevenly distributed. The method of sampling is subject to some variation depending on the character of the ore, but the usual method follows:

The ore is all crushed to 1-in. size and divided into halves, alternate shovelfuls being taken to the storage bins and to the rolls, which are set to crush to ½ in.

The metallics on the screen are collected, weighed, melted and cast into bars. The bars are weighed, sampled and assayed. The ore passing ½-in. screen is made into two piles of equal weights by alternate shoveling, one man doing the work. Each pile constitutes a sample and is treated separately as follows:

The ore is coned three times in order to mix it thoroughly, then coned and quartered until the weight is about 2400 lb. This amount is crushed by rolls to pass a ¼-in. screen.

This product is coned three times to mix thoroughly, then quartered and coned until reduced in weight to from 400 to 600 lb. The ore is then crushed in rolls to pass 1/10-in. screen. Any metallics are ground in a drug mill to pass the 1/10-in. screen. The sample is then cut down by the use of a Jones sampler to about 75 lb. This is then ground to pass a 1/20-in. screen and reduced by the Jones sampler to about 5 lb. The sample is ground fine in a pebble mill, screened on a 120-mesh screen, giving 120-mesh "metallics" and "pulp."

The other half of the ore (through ½-in.) is sampled in the same manner as described above. Both sets of samples are assayed and results averaged. If the ore is very rich (over 1000 oz. Ag per ton) it is divided into three parts after passing through the ½-in. screen. Each part is then run down separately. Small amounts of metallics on ¼-in. screen are ground up in a drug mill and returned to the sample. Larger amounts are melted into a bar and the bar assayed.

Method of Assaying.—There have been at least three distinctly different methods in use for assaying these arsenical cobalt-silver ores.

(a) The combination of wet and fire assays.
(b) The scorification fire assay.
(c) The crucible fire assay.

The writer has had best success with method "(c)." The manipulations are fewer and simpler than in "(a)" and the loss of silver by volatilization has been found to be more perfectly controlled than in either of the other methods. We know, however, that other assayers use methods "(a)" and "(b)" with excellent results. We shall describe only our own practice.

The Crucible Fire Assay.

Fluxes (a) silver ore flux:
Soda ash (Na_2CO_3).....4 parts
Pearl ash (K_2CO_3).....4 parts
Borax glass ($Na_2B_4O_7$).....2 parts.
(b) Litharge.
(c) Borax glass for cover.

Assay of Low-Grade Ores.

Fusions are made in a gas-fired muffle furnace (Case type with fan blower attached). "20-gram," "Denver" or "Battersea" crucibles are used. Six assays are run at once with two empty crucibles in front.

Charge:

Pulp	0.2 A. T.
Silver flux	30 grams
Litharge	60 grams
Flour	1 gram
Borax glass cover	8 grams.

Mix the charge by rolling on a rubber cloth and transfer to crucible. Cover with the borax glass. Place crucibles in muffle at medium red heat. Hold for 20 minutes, then close muffle door and raise temperature to bright yellow and hold for 30 minutes. Pour into conical iron molds and when solidified hammer free from slag.

Cupel on single rows across the muffle. The temperature and draft control are the important factors. The temperature is kept as low as possible and conditions must be freely oxidizing without excessive draft.

The temperature must be low enough at the finish so that litharge feathers form on the cupel around the button. Large silver buttons after the "blick" are covered with hot cupels. Small buttons are simply cooled slowly to avoid "sprouting."

"Metallics" are run separately by scorification, using test lead with borax glass and silica flux (equal parts borax glass and sand, both ground fine). Temperature control both in scorification and cupellation are vital.

"Silver bars" from nuggets or coarse "metallics" are sampled by drilling top and bottom. The drillings are assayed for fineness. Three hundred milligrams are wrapped in pure sheet lead and cupelled with a pure silver proof beside it. The weight of silver taken for the proof is 85 to 90 per cent of the weight of the drillings of the sample (250 to 270 m.g.). The percentage loss of silver suffered by the cupelled proof is added to the silver recovered by cupellation of the drillings.

Assay of High-Grade Ores.

Charge:

Pulp	0.2 A. T.
Silver flux	30 grams
Litharge	90 grams
Flour	none. (The ore is a reducer.)
Borax glass cover	8 grams.

Fusion is made as in the case of low-grade ores. The larger quantities of "metallics" from high-grade ores are best assayed by the crucible process rather than by scorification.

Charge:

Metallics	0.5 gram
High-grade ore flux	50 grams
Flour	1 gram

Calculation of Results.

Let x = total weight of sample (a) pulp; (b) metallics
" y = assay of pulp (ounces Ag per ton of pulp)
" z = milligrams of Ag in total weight of metallics.

Then $\frac{(a)}{x}$ = per cent pulp, and $\frac{(b)}{x}$ = per cent metallics.

Then $\frac{x}{29.166}$ = A.T. (assay tons) of sample.

Then (1) y ... per cent pulp ... ounces Ag per ton of ore (from pulp sample).

Then (2) ... ounces Ag per ton of ore (from metallics.)

(1) plus (2) = ounces Ag per ton of ore (total).

If there is a bar of silver made from coarse metallics or nuggets, it is usually paid for on the basis of its weight and assay value. If the total original assay value of the ore is to be calculated, it must include the Ag in coarse metallics.

This involves the factors:

Per cent of coarse metallics or nuggets.
Weight of bar from nuggets.
Per cent of screenings from nuggets.

The calculation is easily made.

Agreement Between Assayers.

The following figures illustrate how well independent assayers agree as to the value of samples of these complex ores prepared by the methods described.

Mark			
37396	*Seconds*		
	Pulp	74.25 ounces	...
	Metallics	61.96 "	62.79 "
	Total.....	136.21	136.32 "
	Fines		
	Pulp	114.23 ounces	114.42 ounces
	Metallics	28.23	28.22 "
	Total	142.46	142.64 "
37691	Total.....	54.05	53.79 "
37252..	*I.C.A.*		
	Pulp	1225.85	1225.00
	Metallics	1295.53	1293.95
	Total.....	2521.38	2518.95
37252	*H.G.*		
	Pulp	503.17	502.14
	Metallics	558.34	559.24
	Total	1061.51	1061.38

These agreements are exceptionally close and represent a high degree of skill in manipulation acquired by the operators, especially in the close control of cupellation losses.

The methods of sampling and assaying are almost entirely those worked out by the Pennsylvania Smelting Company. Their accuracy has been confirmed by repeated re-sampling and re-assaying.

Copper-Zinc Alloys.—A paper by **Wilder D. Bancroft** and **J. M. Lohr** of Cornell University, gives the results of an investigation made to establish the relationship between the constitution of the copper-zinc alloys, and the tensile strength of the cast metal, unworked and without heat-treatment.

Brasses containing 100 to 47.5 per cent copper were tested. The microscopic examination showed that the alpha-phase exists as far as 66 per cent copper. The alpha + beta phase extends from this point to about 57 per cent copper, while the pure beta-phase occurs between 57 and 50 per cent copper.

The changes in the tensile strengths of the alloys agree very well with the changes in the internal structure as brought out microscopically. The values remain pretty uniform throughout the alpha-field and increase very rapidly when the beta-phase begins to appear, at about 66 per cent copper. As the proportion of pure beta metal increases the strength continues to increase until a maximum is reached in the field for pure beta. When the brittle gamma metal makes its appearance the strengths decrease rapidly.

The maximum tensile strength occurs in the neighborhood of a 55 per cent copper alloy, and its value is about 71,000 pounds per square inch.

"It is possible to obtain a cast brass having an ultimate tensile strength of 71,000 pounds per square inch, and an ultimate elongation of 1.48 per cent, or a brass having an ultimate tensile strength of over 36,000 pounds per square inch and an ultimate elongation of 35.6 per cent."

Adsorption of Coloring Matter.—A paper in French by **A. Bouchonnet,** of Paris, France, deals with the adsorption of coloring matter of ochres. The author investigates the factors which can accelerate or retard the adsorption, namely, temperature, concentration, acidity, etc.

Errors in Gas Analysis Resulting from the Assumption that the Molecular Volumes of All Gases Are Alike.—A paper by **George A. Burrell** and **Frank M. Seibert,** of the Bureau of Mines, Washington, D. C.

The authors submit actual calculations from gas analyses they have performed in which is shown the need for correcting well-known equations so that the errors which result from the assumption that the molecular volumes of all gases are alike will not occur.

The best density determinations made of the common gases were chosen and the reactions for complete combustion with oxygen of carbon monoxide, methane, ethane, propane, etc., were changed accordingly.

The combustible constituents in natural gases are changed in some cases as much as 2 per cent when the correct equations are used.

The application of the study consists in the use of the corrected equations when analyses are made of gas mixtures containing high percentages of combustible gases.

Section on Fuels and Asphalts.

Neutral Coke.—A paper by **J. R. Campbell** of Scottdale, Pa., gives details of a neutral coke test made at the Gary coke plant in order to investigate the claims of the Diehl-Faber process for making neutral coke. In this process, by the introduction of limestone into the charge in certain proportions, it is claimed that the sulphur in the raw coal is transformed into calcium sulphide during the coking process, and that the physical quality of the resultant coke is improved. The effect the limestone will have upon certain by-products, *i. e.*, the gases and the ammonia yield, was also investigated; also the temperature conditions that must prevail to secure the desired results. The results of these tests are given in tables or diagrams and the final conclusions are as follows:

The temperature of the coking mass is insufficient for the complete transformation of S in the coal to CaS in the coke during the coking process, and such temperature must be over 2100 deg. Fahr., perhaps nearer 2500 deg. Fahr.

The temperature is insufficient for the complete formation of lime silicates.

It is not practicable to use more limestone than will combine with the ash of the coal to form a mono-silicate.

The physical quality of the coke is improved by the limestone additions if too much free CaO does not remain in the coke and if such additions are for the formation of a mono-silicate, as evidenced by the physical tests of the coke and its physical appearance, provided always that high temperatures prevail at or near the close of the coking process.

The decomposition of the limestone and the action of the resultant gas on the incandescent coke, forms high percentages of CO gas, which lowers the B.t.u. value of the whole gas about 10 per cent.

The coking time will be extended by the introduction of limestone into the charge, if any beneficial results are to be expected

The total NH_3 yield will be increased quite materially as evidenced by bomb tests.

To attain sufficiently high temperature in the coking mass for the desired chemical reaction and permanent physical qualities in the coke, will necessitate maintaining the flues at critical temperatres say: 2700 deg. F. to 3000 deg. F.

The Diehl Faber process has but little practical value from a blast-furnace standpoint, unless all the sulphur is converted to CaS during the coking process, or unless a silicate is formed, for the reasons that S other than CaS will enter the iron readily and that the free CaO will cause the coke to crumble upon exposure to the atmosphere.

The results of bomb tests are given in a separate report. The conclusions are:

If "neutral coke" were made from washed Rend coal the gas and sulphate yields would be increased, per ton of actual coal charged, due to well understood chemical reactions.

The percentage of combined NH_3 is radically decreased by the limestone additions.

While the volume of gas is increased by the limestone additions, the B.t.u. value is decreased; consequently, there will be a smaller percentage of available gas.

Purifying Coal Gas with Recovery of By-products.—A paper by **Karl Burkheiser** of Hamburg, Germany, describes the Burkheiser wet desulphuretted hydrogen, cyanogen, and ammonia purifying and recovery process.

The object of the Burkheiser process is to absolutely purify coal gas and to combine the sulphur contained therein with the ammonia so as to form ammonia salt. In the development of his process the author started from the principles used up to now for the sulphuretted hydrogen purifying by the use of bog ore. But he submits the bog ore before its use to a preparation by roasting, and thereby removing all the organic parts, and also by withdrawing from it part of the chemically combined waters. From the original bog ore ($Fe_2(OH)_6$) is formed a red modification, poorer in water (probably from the combination $Fe_2O_3H_2O$), which has a great absorbing capacity for the sulphuretted hydrogen. By so doing it is not only possible to confine the gas purifying itself to the smallest imaginable space, but also to give the purifying mass a form which gives, in the oxidation of the iron sulphide combinations to SO_2 and SO_3, an absolutely pure SO_2 and SO_3.

The fundamental principles of the process consist, in short, of completely removing, by means of the above-mentioned purifying mass, the sulphuretted hydrogen from the gases, and in the regeneration of this purifying mass to drive the oxidation up to sulphur dioxide and sulphur trioxide, and then to wash out by one and the same wash fluid the so-formed sulphurous acids as well as the ammonia of the gases without the carriers of these two products coming in contact.

The paper describes the different steps of the process in some detail.

Refining Light Oil.—A paper on "coal tar light oil in the United States: the manufacture, nature and uses of products derived therefrom," by **John Morris Weiss**, of New York, N. Y., gives a summary of the present status of refining light oil in the United States.

Up to the present the manufacture of products in this field has been mainly confined to materials already existent in the crude oil, and capable of being isolated by physical and simple chemical means. The further, more intricately chemical manufacture of the various derivatives of benzene, toluene, naphthalene, etc., which serve as raw materials for dye manufacture, has as yet been only carried on in a comparatively small way in the United States.

The chemical possibilities along these lines are yet to be developed in this country, and here, indeed, is a wide field for technical endeavor which will place the coal tar industry of the United States in a stage of development equal to that already attained abroad.

Coal Preparation.—A paper by **W. S. Ayres**, of Hazleton, Pa., discusses "the technical problems of coal preparation." The preparation of coal, whether anthracite, bituminous or other lignite, or any of the grades between or beyond them, must make use of the same laws, namely, those governing the difference in specific gravity and those governing the difference in the angle of repose. One of these groups may be perfectly efficient in preparing one coal having certain physical characteristics, while for another coal the other group would do perfect work, and for almost infinite mergings of the two typical classes of coal a series of combinations and modifications of the two principal methods would have to be employed.

In the specific gravity process of preparation, typified in the jig, many perplexing problems have arisen and many annoying results are always present, depending for their degree of seriousness upon the physical nature of the material being treated.

Of the other mechanical devices for removing impurities from coal there are three that are extensively used, each employing the difference in the angle of repose between slate and coal as the basic principle of its operation. These three systems are described.

The most important of all features in the entire process of anthracite preparation is to so handle the coal in transportation, screening, separation, conveying and loading as to retain the pieces of coal whether coming directly from the mine or from the crushing-rolls in their initial form without any loss in weight from abrasion or chipping, if at all possible to do so. This must be taken into consideration in the transportation and loading of the coal, etc.

Low-Grade Lignite Coals.—A paper by **E. J. Babcock** of the University of North Dakota, gives an account of extended "investigations relative to the better utilization of non-coking low-grade lignitic coals."

There are enormous Western lignite deposits. North Dakota alone has a coal area of over 32,000 sq. miles, capable of producing 400 or 500 billion tons.

The author's extended researches indicate that the concentration of the raw lignite into a fuel of relatively high heating values depends upon, first, the removal of the moisture; second, the expulsion and saving of the volatile gas, and, third, the binding together of the concentrated residue into a strong, durable, and satisfactory briquetted product. The best utilization of these lignites is therefore a combination of briquetting with gas production, while in addition there is a considerable amount of ammonium sulphate formed (nearly 15 lb. per ton of dry lignite) and tar, both of which have a ready market.

One and one-half tons of lignite will produce about a ton of these briquets in addition to 12,000 or more cubic feet of gas. The briquets have above twelve-thirteenths the actual heating value of average anthracite and can be made at a sufficiently low cost to put the industry on a commercially satisfactory basis in at least some of our Western states.

Considering the ease with which the gas is produced, the low price of the original lignite, and the value of the residue, this gas should have a large commercial value for heating, lighting, and power purposes because of the low price for which it could be sold if manufactured in a plant used to produce briquets from the residue.

The Constitution and Genesis of Certain Lignites and Sub-Bituminous Coals.—A paper by **Reinhardt Thiessen**, of the Bureau of Mines, Washington, D. C. Coals are composed chiefly of a residue of the most resistant components of plants, of which resins, resin-waxes, waxes and higher fats and alcohols are the most important.

Plant substances differ very markedly in their resistance to various agencies. These substances involved in the life and the support of the plant are relatively labile, whereas those involved in some protection function, or are to be looked upon as waste products, are relatively stable. Of these substances, the resins, waxes, resin-waxes, higher fats and alcohols are the most stable.

After the death of the plant there begins, governed by various conditions imposed upon the deposit, a partial decomposition, maceration, elimination and chemical reduction, brought about chiefly by the agencies of organisms, fungi

first, followed closely by bacteria. The least resistant components are removed first, leaving the more and the most resistant behind in a residue called peat.

The process of elimination and chemical reduction begun in the peats, chiefly by biochemical means, is taken up and continued by dynamochemical means into and through the various grades of coals.

Lignites and sub-bituminous coals are therefore composed of a residue or debris consisting of the more and the most resistant plant substances in a macerated and changed condition, in which are usually embedded logs, stems, branches, or fragments thereof, also in a much changed condition, in varying proportions.

The "wood" has been reduced very much, and since its resin contents have suffered little if any change, it has become very resinous.

The debris is composed (a) of cellulosic substances in a greatly altered condition, in the shape of fragments of tissue, small complex of cells, single cells and fragments of cells; (b) resinous substances; (c) cuticles; (d) spore-exines; (e) pollen-exines, and (f) a variety of a small number of other unimportant bodies. The interstices of these bodies are in turn filled in with a still finer originally macerated matrix consisting essentially of the same substances, either in a very high state of comminution or the residue of them. This component is termed the ground or binding mass.

Highly macerated leaf cuticles are an important component of the ground mass.

The proportion, or distribution, of the various bodies named, varies considerably in different beds and in different layers of the same beds.

The ratio of the cellulosic components to the resinous and cuticular components varies, generally, inversely to the state of maceration and the degree of metaphorism of the coal.

Section on Physical Chemistry

Temperature Scale.—A paper by **George K. Burgess,** of the Bureau of Standards, Washington, D. C., on "the present status of the temperature scale," discusses the thermodynamic scale, the gas scales, secondary methods and scales, and the calibration of the platinum resistance thermometer and the thermoelectric thermometer. The following list gives standard temperatures in the thermodynamic scale. Boiling points are for a pressure of 760 mm. Hg.

STANDARD TEMPERATURES. THERMODYNAMIC SCALE.

Substance	Phenomenon	Temperature C°	Uncertainty C°	Reproducibility C°
Hydrogen	Boiling	−252.7	0.2	0.05
Oxygen	Boiling	−182.9	0.1	0.03
Carbon dioxide	Sublimation in gasolene	−78.34	0.1	0.03
Mercury	Freezing	−37.7	0.1	0.05
Water	Freezing	0	0	0.001
$Na_2SO_4+10H_2O$	Transformation to anhydrous salt	32.383	0.002	0.001
Water	Boiling	100	0	
Naphthalene	Boiling	271.96	0.02	0.01
Tin	Freezing	231.85	0.1	0.05
Benzophenone	Boiling	305.90	0.05	0.02
Cadmium	Freezing	320.92	0.1	0.03
Lead	Freezing	327.4	0.1	0.05
Zinc	Freezing	491.4	0.1	0.15
Sulphur	Boiling	44.46	0.1	0.03
Antimony	Freezing	630.	0.5	0.3
Ag Cl	Eutectic freezing	779	1.0	1.0
NaCl	Freezing	800	2.0	1.0
Silver	Freezing	960.5	1.0	0.5
Gold	Freezing	1063	2.0	1.0
Copper	Freezing	1083	2.0	1.0
Palladium	Freezing	1549	10	3
Platinum	Melting	1755	15	5
Alumina	Melting	2000	30	20
Tungsten	Melting	3000	100	25
Carbon arc	Pos. crater	3600	150	50
Sun	Surface	6000	500	100

For the temperatures dependent on atmospheric pressures we have:

Oxygen B.P.	$T = T^{760} + 0.013\ (p - 760)$
Carbon dioxide S.P.	$T = T^{760} + 0.017\ (p - 760)$
Water B.P.	$T = T^{760} + 0.037\ (p - 760)$
Naphthalene B.P.	$T = T^{760} + 0.058\ (p - 760)$
Benzophenone B.P.	$T = T^{760} + 0.063\ (p - 760)$
Sulphur B.P.	$T = T^{760} + 0.0912\ (p - 760) - 0.000042\ (p - 760)^2$

As to the chemical purity of the various substances, Mylius has shown that the following metals may easily be had to 0.01 per cent or better: Au, Ag, Pt, Hg, Cu, Sn, Pb, Cd, Zn. Of the boiling substances, benzophenone and oxygen are the only ones to the purity of which special attention need be given.

To show how carefully these standard preparations have been determined, the author gives in detail the results of all measurements since 1900 on some of the most carefully studied of these temperatures, such as the boiling points of oxygen and sulphur and the melting points of cadmium, gold, platinum, and tungsten.

Of course, an international agreement on the temperature scale is of fundamental importance. In pursuance of this idea, the several national laboratories and the International Bureau are at present interchanging communications relative to the establishment by agreement of some such single temperature scale, and it is to be hoped that the outcome of these interchanges will be of great practical benefit and convenience for the certification and use of temperature-measuring instruments, and that thenceforth 500 deg. C. or 1000 deg. C., for example, will each convey but one idea of temperature as do 0 deg. or 100 deg. C., at the present time.

Melting Points of Fire Bricks.—In a paper by **C. W. Kanolt,** of the Bureau of Standards, Washington, D. C., an account is given of the determination of the melting points of 54 samples of fire brick, including fire clay, bauxite, silica, magnesia, and chromite brick. The determinations were made in an electric vacuum furnace, the temperature being measured with an optical pyrometer.

The following melting points of materials important in the manufacture of fire brick were determined:

Kaolin	1740° C.
Pure alumina	2010° C.
Pure silica	1750° C.
Bauxite	1820° C.
Bauxite clay	1795° C.
Chromite	2180° C.

An improved method of calibrating the Holborn-Kurlbaum optical pyrometer is described.

Allotropy of Iron and Silver Iodide.—A paper by **Carl Benedicks,** of the University of Stockholm, Sweden, on the allotropy of iron and silver iodide points out that for the metallography of the iron, its allotropyis still the most vital question. The results of the author's investigation are as follows:

The very common opinion that allotropy means a quite sudden transformation from the one modification to the other cannot, a priori, be maintained except as a special case (Type I). There is always the possibility that the one modification (Type II, a and b) or both (Type III) have a certain solubility for the other—this is the simplest expression for the fact that the transformation partly takes place continuously. If the solubility were unlimited one could not speak of allotropic transformation point, but allotropic modifications can nevertheless be said to occur. (Type IV.) Which of the types of allotropy (theoretically) possible, actually occur in each case, must be decided by experimental study of one, preferably more, of the properties in the proximity of and at a sufficient distance from the transition point in question.

An experimental study of the dilatation of silver iodide, extended to — 180 deg., has shown that the transformation point of this body at about + 147 deg. is an illustration of Type II, a. At low temperatures the silver iodide has a positive dilatation; only at 0 deg. or room-temperature the well-known negative

dilatation occurs, that is peculiar to silver iodide. The dilatation must be ascribed to a solubility increasing with the temperature in the hexagonal modification of the regular modification stable above the transition point, a solubility which, according to the curve of dilatation, is in all probability greatly limited.

The supposition of a certain solubility has earlier been made by Tammann, but for want of clear proofs rejected by Roozeboom; determinations of dilatation at higher temperatures have earlier been made by Rodwell, and though only used for the position of the transition-temperature, they coincide very well with those of the author.

The simple dilatation apparatus used by the author and with which temperatures between —180 deg and 0 deg. could be very conveniently obtained, will probably be of some use on other occasions.

A detailed determination of our physical knowledge of the critical transformation point A, of the iron at about 890 deg. and the lower, more undecided transformation range A_2, shows that likewise the transformation of the iron at 890 deg. belongs to Type II, a, of which we thus know two examples. According to this the nature of the so-called beta-iron is to be alpha-iron (stable at low temperatures) containing in solution a limited amount of gamma-iron, increasing with the temperature (stable at temperatures above 890 deg.).

"The opinion is greatly a returning to the original views of Osmond.

"The standpoint now attained simplifies in a high degree our opinion as to the metallography of iron; this is evident from, amongst other things, that the three theories, now acknowledged as the most probable ones, for the constitution of martensite, when seen from this point of view, become identical."

Magnetic Theory.—A theoretical paper by **Jacob Kunz,** of the University of Illinois, deals with the present theory of magnetism and the periodic system of chemical elements. After an introduction on the fundamental assumptions of the electromic theory in its relation to magnetism, the author sums up the experimental facts with special reference to diamagnetism and additive and non-additive properties. He then discusses the periodic system of the elements and their magnetic properties, and further deals with ferro-magnetism and the magnetom by Weiss and the degrees of freedom.

Synopsis of Metallurgical and Chemical Literature

Gold and Silver.

The Role of Alumina in Copper Slag Formation.—The question of whether alumina acts as an acid or base in slag formation has never been satisfactorily settled in the minds of metallurgists. In his presidential address at the last (June, 1912) meeting of the Australasian Institute of Mining Engineers, MR. H. C. BELLINGER gave a number of examples of the varied manner in which alumina acts under different conditions. At Rossland, B. C., where the gangue contained 14 to 18 per cent alumina, 10 to 12 per cent lime, 2 to 3 per cent potash and soda, and 40 to 46 per cent silica, one metallurgist regarded the alumina as an acid, and fluxed with limestone. His furnace promptly froze; whereupon, assuming that he had not added enough base, he put more lime on the charge, with worse results. Another metallurgist fluxed his charge on the assumption that the alumina in combination with silica would act as a base, and the balance as an acid. This was found to give satisfactory results, and has since been the basis of operations.

In another case at Butte, where it was required to form a slag containing 45 to 50 per cent silica, all of the alumina (8 per cent) acted as a base. Similar experience is cited at the Northport and Britannia smelters. Another instance is cited in which it was difficult to decide which part alumina played. A copper ore contained 40 to 45 per cent barite and 8 per cent zinc. It was necessary to add both silica and alumina, and the resulting slag carried 5 to 12 per cent alumina. All slags resulting from various mixtures were satisfactory, and in some cases the alumina undoubtedly acted as an acid.

Mr. Bellinger concludes, as a result of his wide experience, that mere chemical analysis will not serve to reveal the rôle played by alumina. He cites the diversity in composition of the felspars and mentions their different behavior under similar treatment. Further variations are cited among the meta-, ortho- and hydro-silicates, with the range of oxygen ratios from less than 1:1 in the sub-silicates to 4:1 in the bi-silicates. "It is when one considers the many conditions of combinations in aluminous compounds, and has noted the definite changes in the action of the alumina in sympathy with variations in such combinations, that it becomes quite feasible

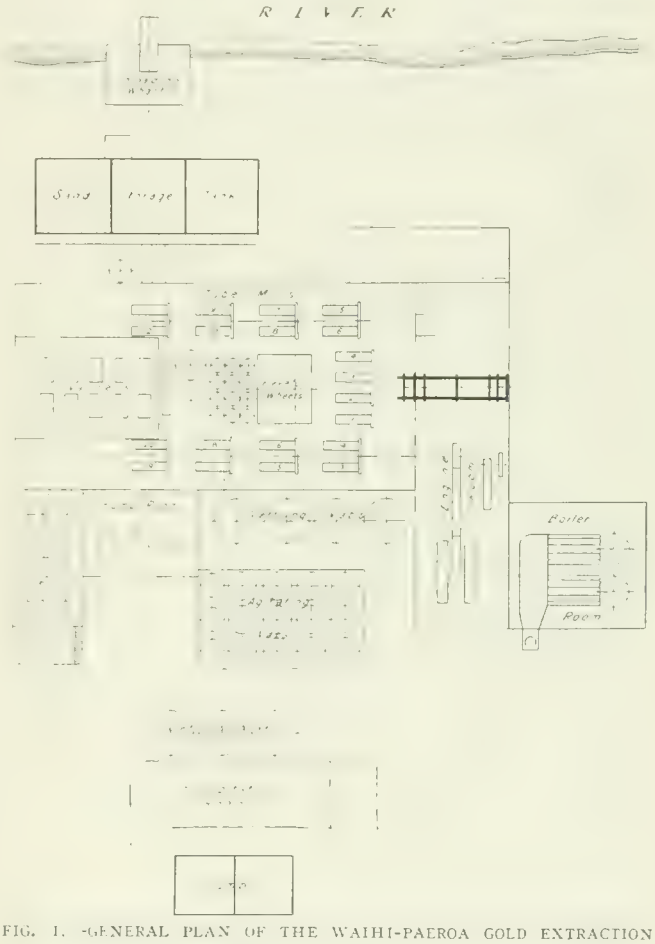

FIG. 1. GENERAL PLAN OF THE WAIHI-PAEROA GOLD EXTRACTION COMPANY'S TAILING PLANT.

that, under similar furnace conditions, we could reasonably expect the compounds to adopt rôles suited to their peculiar forms."

The author cites the fact that under some conditions alumina has been satisfactorily handled by calculating as acid that portion which is soluble in acids, and the insoluble portion as base or as an independent elementary magma.

Cyaniding Tailing.—With improvement in metallurgical methods, instances of re-treating old tailings are multiplying. In the August, 1912, issue of the *Mining Magazine*, Mr. CHARLES A. BANKS describes a plant which he erected for the Waihi-Paeroa Gold Extraction Co., of Auckland, N. Z., to cyanide 500 tons per day of quartz tailing which had accumulated for the past 20 years in the lower reaches of the Ohinemuri River.

In Fig. 1 is given a general plan of the mill. A dredging plant is used to raise the tailing from the river by an air-lift

of 100 tons per hour capacity. The sand thus elevated is transported by barges to the unloading wharf, where it is screened to remove coarse rubbish and then stored in concrete bins of 3000 tons capacity.

The treatment begins by separating the light river sand and charcoal from the valuable quartz. This is accomplished on vanners, the quartz passing over the head of the machine in a layer about ¼ in. deep, where it is washed off by a weak cyanide solution. The quartz is then ground in tube mills, the tube discharge being elevated to a classifier by means of two tailing wheels having a combined lift of 35 ft. The fine overflow from the classifier is all minus 200-mesh, and is run to settling tanks. The coarse underflow is returned to the tube mills.

The slime is settled with lime and then agitated by air in cone-bottom agitators, 50 ft. high and 13 ft. diameter. The period of agitation is 48 hours. After agitation the slime is filtered under a vacuum of 18 in., forming a cake 1½ in. thick weighing 9 tons, in about 15 minutes. The cake is washed for 18 minutes and then discharged by compressed air. One crane with one pulp and two washing vats 20 ft. diameter, and two filter baskets each of 1660 sq. ft. area, can easily treat 500 tons in 24 hours. Zinc shavings are used for precipitation.

It will be noticed in the general plan of the mill that the tubes are placed around the tailing wheels. This convenient arrangement is made possible by a new method of driving sixteen of the tubes, arranged in two sets of two rows each. A main shaft runs between each pair of rows. Four pinions on each shaft are keyed to friction clutch sleeves, and may be engaged or disengaged quickly and satisfactorily. Each pinion engages two tube mill spur wheels. As the tubes are placed on sole plates with adjusting screws, any one of them may be run out of gear when necessary without interfering with the work of the other.

Mr. Banks has found this method of driving superior to the use of tight-and-loose pulleys and cites the following advantages: (1) Smaller building; (2) mills closer to elevator wheels, and therefore less height to elevate the pulp; (3) saving in capital expenditure and operating cost; (4) no belts; (5) main shafts on ground instead of up on trestles; (6) a balance pinion, the pinion practically floating as it works.

The tubes are 16 ft. long and 4 ft. diameter, run at 27 r.p.m., and require 27 hp. when carrying a load of 4 tons of pebbles. Their capacity is 25 tons per tube in 24 hours, grinding to 200-mesh.

The average assay value of the material treated is 11s. 6d. ($2.75), and it is expected that the tailing will be reduced to a value of only 2s. 6d. ($0.60), with an operating cost of not more than 3s. 3d. ($0.80) per ton, which will leave a margin of profit of about $1.35 per ton. The mill cost about $340,000. No statement is made of the amount of river tailing available.

Cyaniding Concentrate.—A series of tests was made to determine the advisability of cyaniding raw concentrate instead of shipping it to a custom smelter. The results are communicated by Robert Linton in the July, 1912 *Journal* of the Chem. Met. & Min. Soc., of S. Africa.

The analysis of the concentrate was as follows:

Insoluble	44.00	per cent
Fe	26.50	"
Cu	1.30	"
Zn	1.20	"
MnO	0.41	"
Al_2O_3	1.40	"
CaO	1.75	"
MgO	0.47	"
As	0.03	"
S	18.20	"
Ag	4.20	"
Au	0.06	"

The silver occurred as argentite and the gold was contained in the silver sulphide. The concentrate was ground to 200-mesh and agitated with cyanide solution in a small Pachuca tank. The first test showed a constantly increasing alkalinity in the solutions used, although no lime was added after commencing agitation. An analysis of the solution after agitating five hours showed no alkaline sulphides, although K_2S probably formed and immediately combined with KCN to form KCNS. This would seem to explain the increase in alkalinity observed and to indicate that the increase in alkalinity involved a direct loss of cyanide.

Tests to see whether lead acetate would reduce the cyanide loss showed that with 1 per cent, or over, of acetate, the alkalinity gradually disappeared, but the consumption of cyanide greatly increased.

The results of all the tests seemed to indicate that the most economical treatment was to grind the concentrate in a solution of about 0.2 per cent KCN, then agitate in a 0.6 per cent KCN solution, raising to about 0.8 per cent KCN toward the end of the treatment. A high protective alkalinity seemed to be of no advantage, about 0.1 to 0.15 being sufficient. Lead acetate seemed to be of no value in preventing the destruction of cyanide, although the use of a small amount served to keep the solution clear.

Copper.

Electrolytic Copper Refining.—In the course of a report on the 1912 meeting of the Australasian Institute of Mining Engineers, the *Mining and Engineering Review* (Australia), for July 5, gives the following account of refining operations at the plant of the Electrolytic Smelting & Refining Company, Port Kembla, N. S. W.

The tank house building is constructed entirely of wood above the cellar level. The tanks number 600 and are 10 ft long, 3 ft. 6 in. wide and 3 ft. 7 in. deep. They are built of Oregon lumber and lined with 6-lb. lead. The arrangements of tanks is in sections of 30 and 60, set 10 wide and 3 deep, the lowest tank in the series being 7 ft. above the cellar floor. Pohle air-lifts and hard-lead centrifugal pumps handle the electrolyte. The heater boxes are equipped with hard-lead pipes carrying exhaust steam. Live steam is used to make up loss by evaporation.

The desired composition of the electrolyte is 14 per cent $CuSO_4.5H_2O$ and 12 per cent H_2SO_4, with a sp. gr. of 1.18 and a temperature of 130 deg. F.

The anodes are brought to the tank house on racks, spaced 5-in. centers as in the tanks. By means of a crane and lifting hooks, a full tank load of twenty-one anodes is lifted at one time and placed in the tank. A similar rack is used for lifting the twenty-two cathodes from the tank. The tank house has a capacity of about 2000 tons of copper per month.

About 14 per cent of anode scrap is made. The current density is from 16 to 18 amp per sq. ft. of anode surface. The slime containing gold and silver is sluiced from the bottom of the tanks into boxes, and after being screened through a 30-mesh sieve, is blown through lead pipes to the refinery.

Thirty tanks are in use for making starting sheets. These weigh about 7 lb. each. About 20 per cent of the sheets are sheared into strips 4 in. wide, to form lugs for the remainder.

The refining of the gold-silver slime is done in lead-lined agitators 5 ft. high and 5 ft. diameter, fitted with hard-lead propellers. As received from the tank house, the slime contains from 30 to 40 per cent copper and is agitated with sulphuric acid and leached until it contains less than 1 per cent copper before being discharged. The slime is then washed, dried and melted into doré bars for electrolytic refining.

Ore Roasting.

Decomposition of Metallic Sulphates.—An investigation in this subject has been made by **H. O. Hofman** and **W. Wanjukow** of the Massachusetts Institute of Technology, Boston.

and is published in the September, 1912 *Bulletin* of the American Institute of Mining Engineers.

Most metallic sulphides, when given an oxidizing-roast, pass through the state of sulphate before they are converted into oxides. All metallic sulphates are completely decomposed by heat, with the exception of those of lead and bismuth, but the temperatures at which decompositions take place vary with the metals. Some metallic sulphates are converted directly into oxides, others first form basic salts. Alkali-earth sulphates show a behavior similar to that of metallic sulphates, while alkali sulphates do not part with their sulphur trioxide even at elevated roasting temperatures.

There are four methods of making these determinations. 1. Heating in an evacuated tube; 2, heating in a tube closed at one end, without air current; 3, heating in a crucible with air-current; and 4, heating in an open tube with air-current.

The results obtained in the first three methods are not exactly comparable to the conditions existing in the roasting of the ores. The authors, therefore, have used the fourth method, as it resembles more closely than any other the roasting operation on a large scale. The substance to be tested is placed in a boat inserted into a horizontal tube impervious to gases; the thermo-couple is held near the boat or the substance; the tube is heated gradually, usually by electrical means; a slow current of purified and dried air is blown through and carries away the gaseous products of decomposition; the latter can be tested chemically whenever this seems desirable.

One manner of carrying out this process is to make first a blank test, using the amperage necessary to reach a desired temperature, with the thermo-couple held in the boat, but out of contact with the substance; to record the rise of temperature for given intervals of time, 30 or 60 seconds, and to plot the data which will furnish a smooth curve. The next step is to charge the boat, raise the temperature in the same manner as with the empty boat, record the rise in temperature for the same intervals of time, and to plot the data. Any deviation of the second curve from the first will show that some change has taken place; there will have been a transformation if the weight of the substance has remained constant, a chemical change if the weight has increased or decreased.

The plan of the investigation was to determine the dissociation-temperatures of anhydrous metallic sulphates, the formation of basic sulphates, the characters of the resulting products, and the speeds of reaction at different temperatures, in order to obtain data applicable to roasting operations.

The furnace used for heating was an electric resistance type furnace similar to the well-known Heraeus furnace employed by Hofman and Mostowitsch in their work on calcium sulphate. The current used was 110 volts. It passed through the ammeter and two resistance coils, one for rough and the other for close regulation. With all the resistances turned on the current was 2 amp.; when all turned off the strength was 18 amp. and the latter sufficed to attain a temperature of 1150 deg. C.

The authors give a detailed record of the results obtained in testing a large number of sulphates. The amount of heat necessary to decompose the several anhydrous sulphates vary greatly. Some are dissociated at low temperatures and others at high. The results are assembled in tabl I. in which they are arranged in the order in which they are dissociated with increasing temperatures.

Considering the formation of basic salt from the point of view of the periodic system it appears that in each group the tendency to form basic salts increases with the rise of the atomic weight. Independently of the periodic system the following characteristics are noted:

Normal sulphates which do not form basic salts upon dissociation show both SO_2 and SO_3 in the gaseous product; normal sulphates which form basic salts upon dissociation evolve only SO_2 when they pass from the normal to the basic state basic

Desulphatization of Anhydrous Metallic Sulphates.

Metallic Sulphates	Temperature of Beginning of Decomposition.	Temperature of Energetic Decomposition.	Products of Decomposition.	Remarks.
	Degrees C.	Degrees C.		
$FeSO_4$	167	480	$Fe_2O_3.2SO_3$	Yellow-brown.

$CdSO_4$	827	846	$5CdO.SO_3$	White.
$5Bi_2O_3.4(SO_3)$	870	890	$Bi_2O_3(?)$	Yellow.
$5CdO.SO_3$	878	890	CdO	Black
$MgSO_4$	890	972	MgO	White.
Ag_2SO_4	917	925	Ag	Silver white.
$6PbO.5SO_3$	952	962	$2PbO_2SO_3(?)$	White to yellow.
$CaSO_4$	1,200	...	CaO	White.
$BaSO_4$	1,510	...	BaO	White.

sulphates upon dissociation into MO set free only SO_2; metallic sulphates with bases M_2O_3 and M_2O do not form basic sulphates upon dissociation; the former set free SO_3, the latter SO_2.

Mill Practice.

Elevator Buckets.—The wear on elevator buckets is a considerable item of expense in the operation of concentrating mills. Mr. H. J. Maguire, of Wallace, Idaho, has studied the life and service of elevator buckets and has endeavored to devise an adjustable lip which will be of material advantage. This device is described in the September, 1912 issue of the *Bulletin* of the American Institute of Mining Engineers.

The wear of the bucket is confined to the lip and the corners which have to pick up the material. When the lip on the corner of a 7-in. by 12-in. malleable cast-iron bucket is worn down about 3 in., the bucket is of no further value as a carrier and has to be replaced. The worn bucket, containing about three-quarters by weight of the metal of the original bucket, has a

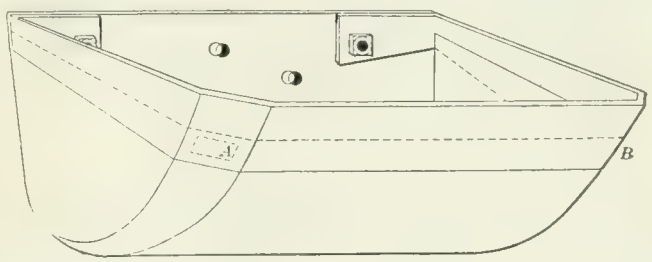

FIG. 1.—ISOMETRIC PROJECTION OF BUCKET WITH LIP ATTACHMENT SHOWING THE LIP BOLTED TO BUCKET.

scrap value of about 10 per cent of that of the new bucket. To the cost of the bucket, however, should be added the time-cost of replacing the old bucket by a new one. This time-cost is considerable when the loss per hour to cease operating the mill, is about $200.

It is out of the question to put lips on a bucket unless the latter was originally fitted with this device. For if it is attempted to fit lips upon buckets nor originally provided with them, it will be necessary to drill holes for rivets and then spend considerable time fitting the lips to the irregular contours of the worn buckets. The improvement suggested is an adjustable attachment which can easily be fastened to, or removed from, the base of a bucket without the use of rivets. This attachment, to be made of a high-grade steel drop-forging or casting, will combine toughness, hardness, and tensile strength. The base of the bucket may be a cheap casting, possibly ordinary cast-iron. This combination of lip and base will not increase

the cost of the improved bucket much, if any, above that of the ordinary bucket now in use, but will increase the life of the bucket, doing the same amount of work, about 400 per cent. with a corresponding decrease in time lost in changing buckets.

This improved bucket is illustrated in Fig. 2, which shows a projection of the bucket with the attachment in place. Two bolts, one on each side of the elevator-belt, pass through the base and attachment and hold both fast to the belt. These end-bolts are 0.25 in. longer than the others. The lip is fitted to the base at the opening at *A* which receives a lug. There is another opening at *B*, which is not shown. Probably a more desirable arrangement than this would be to place the attachment inside the base, in which case the outside of the lip and the inside of the base would be rabbeted.

Recent Metallurgical Patents

Iron and Steel.

Briquetting Flue Dust.—A new method of briquetting flue dust has been patented by ROBERT HUBNER, of Elizabeth, N. J. The object of the invention is to produce tough, porous briquets. The mixture is prepared as follows: 60 parts by weight of flue dust, 7.5 parts alumina clay, 8.4 parts silica, 10 parts lime, 3.5 parts magnesia. These materials are thoroughly mixed, after which there is added 0.6 part hydrofluoric acid, and water in sufficient quantity to convert the mixture into a stiff paste. The mass is then briquetted in any suitable machine.

The percentage of hydrofluoric acid employed depends upon the amount of iron in the flue dust, being increased as the iron increases. Likewise the percentage of silica is dependent upon the amount of silica in the flue dust or in the clay. The addition of the hydrofluoric acid has the effect of producing a fluid slag from which the iron readily separates. (1,038,370, September 10, 1912.)

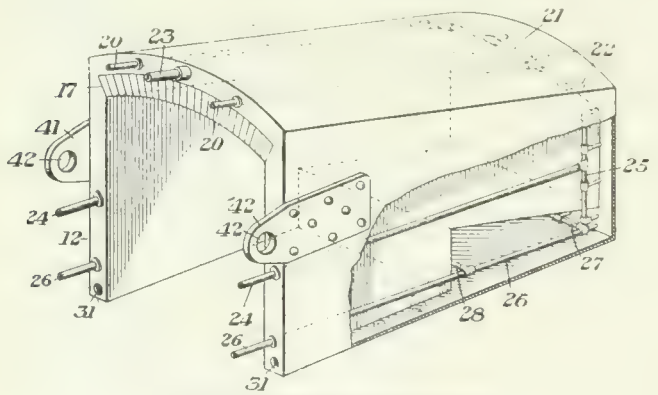

FIG. 1.—WATER-COOLED GAS PORT

Water-Cooled Gas Port.—A novel means for cooling the gas ports of a regenerative furnace is contained in a patent recently granted to LUTHER L. KNOX, of Avalon, Pa., assigned to the Keystone Furnace Construction Company of Pittsburgh, Pa. The water-cooled port is shown in Fig. 1, and its application to the furnace in Fig. 2. The port consists of a hollow metal shell suitably lined with reverberatory material. Inlet pipes are shown at 20, ending in a spray pipe and sprays 21 and 22. Side walls are supplied by pipes 24, also ending in spray pipes at 25. The bottom is provided with an inlet pipe 26, having inner transverse connections 27 and 28. The outlet pipe is shown at 23. Cleaning ports are placed at 31. The entire structure may be readily removed from beneath the arch 9 by means of the side plates 41. (1,038,154, September 10, 1912.)

Gold and Silver.

Cyanide Cylinder.—A proposal to carry on the cyanide process in a cylinder similar to the manner in which the chlorination process was formerly used is contained in a patent granted to HENRY B. MEADE, of Los Angeles, Cal. The inventor has designed a revolving cylinder with an interior filter bottom and a special valve for forcing air, oxygen or solutions into the cylinder under pressure while in motion or at rest.

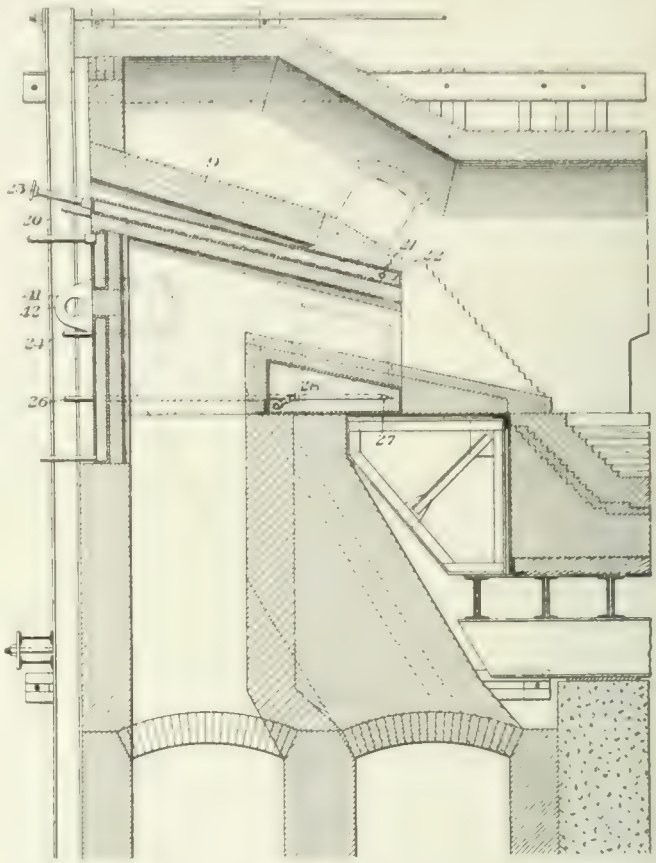

FIG. 2.—COOLED GAS PORT IN REGENERATIVE FURNACE.

Ore is charged and discharged through a manhole, and cyanide solution is withdrawn through a valve below the filter. (1,038,173, September 10, 1912.)

Filter.—A new application of the leaf form of vacuum filter has been patented by CHARLES E. SINGER, of Parral, Mexico. As shown in Figs. 3, 4 and 5, the filter consists of a plurality of leaves vertically mounted on a shaft and suitably connected with a source of pressure and vacuum. Each circular filter is made up of sectors, as shown in Fig. 4. As the shaft revolves the sectors are made to pass through a tank containing the slime which is to be filtered, where a cake is formed in the usual manner. The vacuum is maintained during the revolution of the filter until the sector approaches the discharge launder, where compressed air is ap-

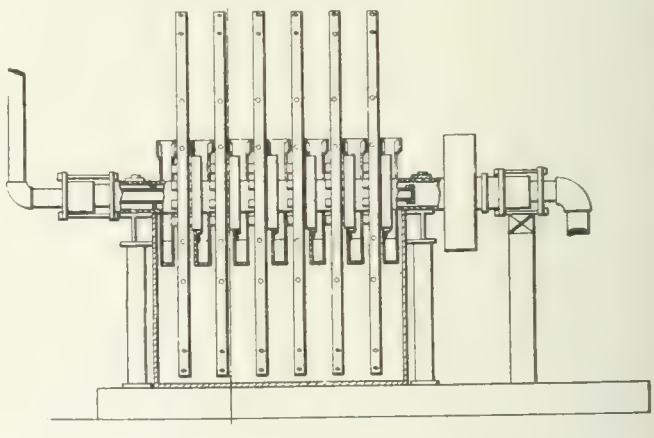

FIG. 3—SECTION OF REVOLVING LEAF FILTER

plied and the cake is blown off into the launder. No provision is made for washing the cake, consequently the filtered pulp must be again mixed with solution or water and retreated on a second machine. (1,017,476, February 13, 1912.)

Slime Filter.—Mr. DAVID J. KELLY, of Salt Lake City, Utah, has recently patented certain improvements on his filtering apparatus, consisting in means for operating a series of presses from a central station; in controlling the traveling of the filter carrier by means of a hydraulic brake; and in using

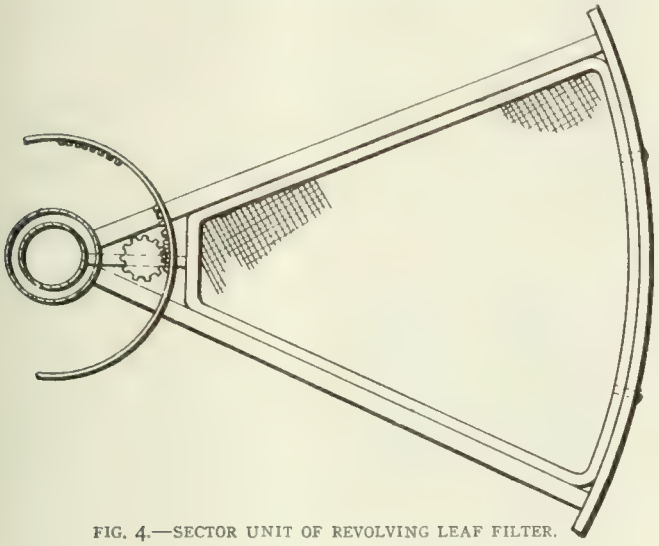

FIG. 4.—SECTOR UNIT OF REVOLVING LEAF FILTER.

a counterweight tank in place of the solid counterweight described in his former patents. (1,015,960, January 30, 1912.)

Copper and Zinc.

Making and Refining Alloys.—The use of boron trioxide as a flux in the manufacture and refining of copper alloys containing tin, zinc, manganese, and so forth, is the basis of a patent granted to WALTER S. ROCKEY and HILLIARY ELDRIDGE,

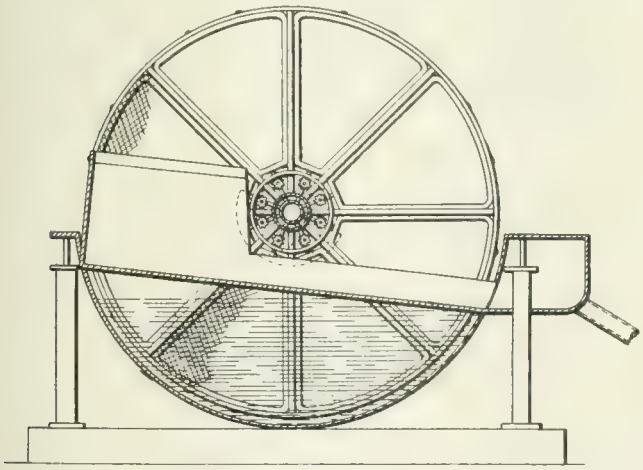

FIG. 5.—SIDE ELEVATION OF REVOLVING FILTER.

of New York City. The method consists in first melting the tin, zinc or manganese under a cover of boron trioxide and then adding molten copper, pouring the latter through the flux. While the copper is being melted before its addition to the alloy metal, carbon is added to assist in the reduction of the oxides that may be contained or formed during the melting. This refining process is further carried on by the boron trioxide flux after the alloy has been made, the molten mixture being maintained at the required temperature until the gases and impurities are expelled. (1,017,629, February 13, 1912.)

Preheater for Zinc Furnaces.—The preheating of the material charged into zinc furnaces is a desirable feature which, however, has not been generally adopted on account of the difficulties usually encountered. It is the object of a recent invention by CARL ORITZHEIM, of Cologne, Germany, to provide a heater which will overcome the difficulties mentioned. The heater is shown in Fig. 6 applied to a vertical muffle. It is designed to feed the charge through the tubes *b*, which are of small sectional area and therefore adapted to heat the charge

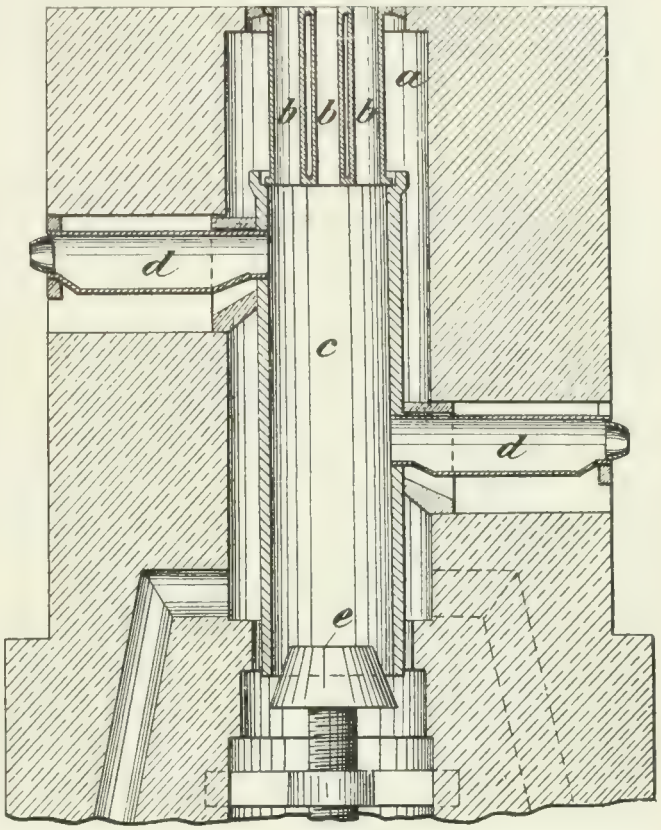

FIG. 6.—CHARGE HEATER FOR ZINC FURNACE.

quickly. From this heater the charge passes into the muffle *c* below. Zinc vapors are condensed in the receivers *d*, while the retort residue is removed continuously or intermittently at *e*. As the charge gradually sinks in the muffle additional ore is fed into the heater. (1,038,205, September 10, 1912.)

Ore Roaster.—A roasting furnace particularly adapted to

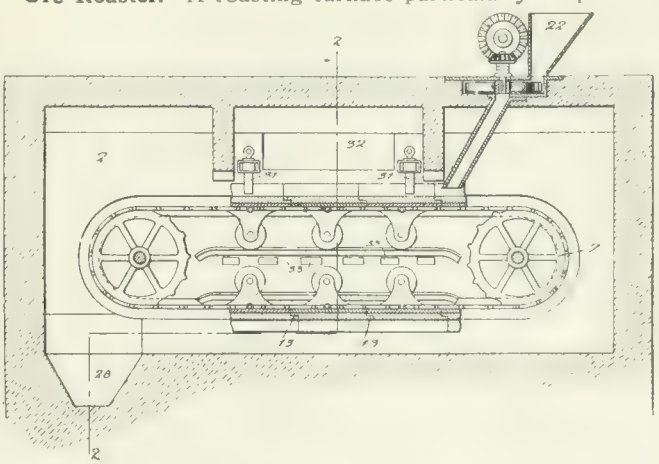

FIG. 7.—ORE ROASTER FOR SULPHURIC ACID MAKING.

the roasting of sulphide ores used in the manufacture of sulphuric acid is shown in Figs. 7 and 8, being the invention of CURTIS C. MEIGS, of Woodbury, N. J. As shown in the cuts, the furnace consists of an enclosed chamber, 2, in which is placed an endless sectional hearth, 13, adapted to travel around two sprocket wheels, 7. The furnace is first heated to the

necessary temperature by means of a fire built within the chamber.

The sulphide ore is then supplied from a hopper, 22, on to the traveling hearth. Air is supplied through openings, 33, and the gaseous products of combustion pass out from a flue, 32, to a suitable acid-making plant, as shown. Rabbles are placed at 31 for the purpose of stirring ore and exposing new surfaces to the action of the air. The speed of the hearth is so ar-

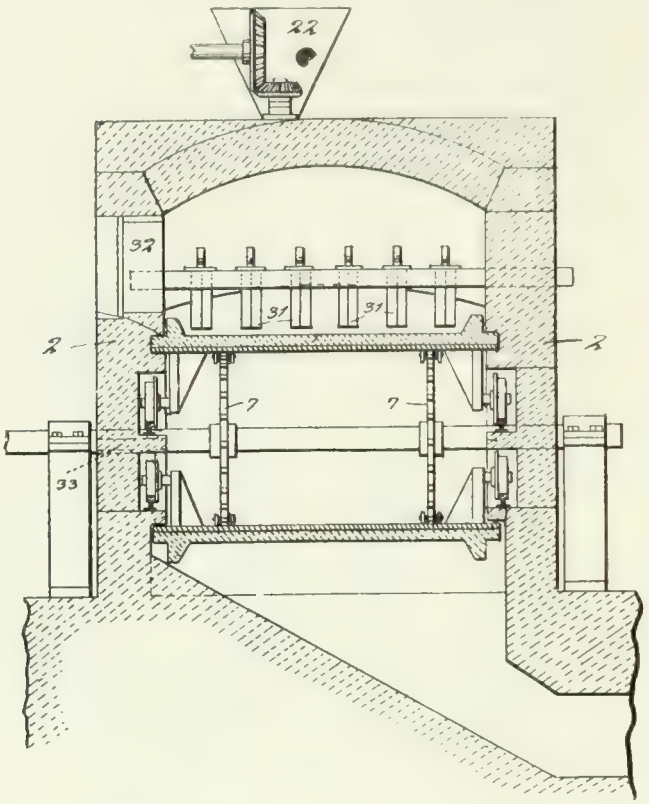

FIG. 8.—SECTION ON LINE 2-2, FIG. 7.

ranged that the roasting operation is completed by the time any section travels from the feed hopper to the point of discharge, where the roasted ore falls into a suitable receptacle at 28. (1,038,408, September 10, 1912.)

Petroleum.

Separation of Oil and Water.—In our issue of June, 1911, page 326, we gave abstracts from patents granted to Dr. Frederick G. Cottrell and associates, of Berkeley, Cal., on electrostatic means for separating water from crude oil. More recently an improvement has been made on the methods formerly described and an additional patent granted to Mr. ALLEN C. WRIGHT, of Berkeley, Cal. Apparatus for carrying out the invention is shown in Fig. 9, and consists of an outer shell, 1, on the inner surface of which are arranged ribs, 4, in a helical course.

The shell then constitues the outer electrode, the inner electrode being the cone 12. The space between the electrodes is filled with the material to be treated, which is fed through the pipe 6.

The outer electrode (the shell) is given a rotary velocity of from 300 to 500 r.p.m. At the same time the material is placed under electrostatic influences, which cause the smallest particles of water to agglomerate. When these particles become of sufficient size to be acted on by centrifugal force they are thrown to the outer shell and forced by the spiral ribs to the bottom of the receptacles, where they are discharged through pipes 9.

The dewatered oil rises and is discharged through pipe 7. (1,034,668, August 6, 1912.)

International Rubber Conference.

The Third International Rubber Conference was held in the new Grand Central Palace, New York, September 24 to 30, 1912. Chemists and engineers, planters and manufacturers and representatives of interests allied with the rubber industry gathered for mutual advantage and benefit. At the meetings which were held, all of the aspects of the rubber business were considered, while the exhibits combined to give tangible evidence of technical progress in an industry which is of growing importance.

Exhibits.

All of the rubber producing countries of the world were represented by wonderful exhibits of wild and plantation rubber

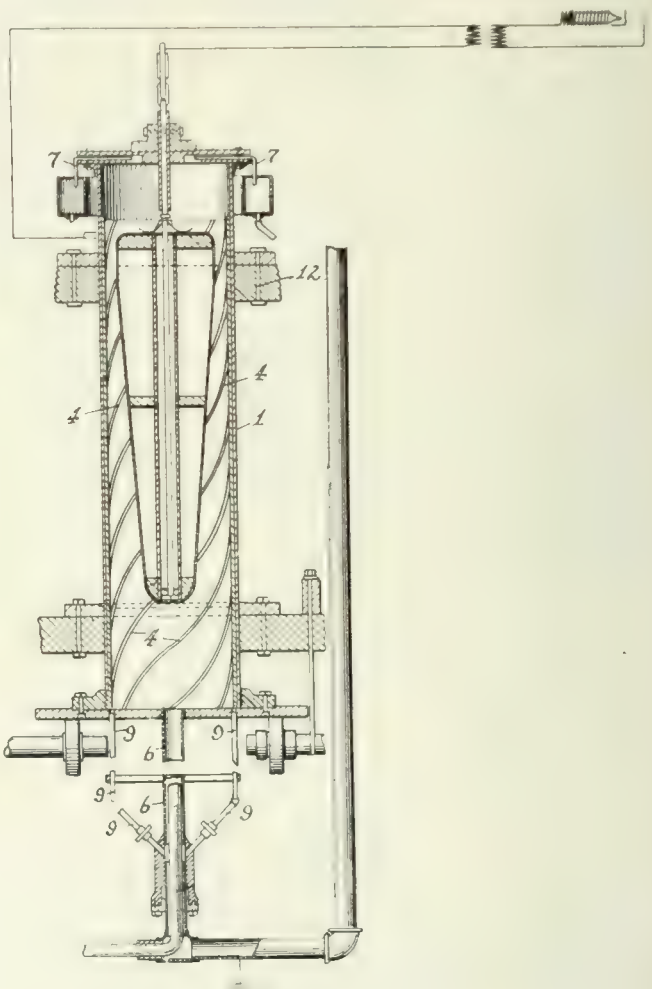

FIG. 9.—ELECTROSTATIC SEPARATION OF OIL AND WATER.

in both the crude and refined state. Brazil easily held first place in point of size and extent of exhibit, showing products from the states of Amazonas, Matto Grosso, Para, Acre, Minas Gereas and Bahia. Other countries having exhibits were, Malay States and Straits Settlements, Ceylon, Hawaiian Islands, Philippine Islands, Burma, Bolivia and Honduras. A cinematograph exhibition at various hours during the day and evening, gave scenes of life and work in the rubber countries.

Of great interest from a technical point of view were the exhibits of companies which make "reclaimed," "regenerated" or "naturized" rubber from old rubber scrap and waste. While the details of many of these processes are kept secret, they consist mainly in disintegrating the old rubber and dissolving the cotton or woolen fabric with acid or alkali, washing and pressing. The product is usually able to compete with the lower grades of primary rubber, like those from Africa. The ten-

sile strength and elasticity of the reclaimed product is less than that of the original.

One of the regenerating systems makes use of an electric current of high amperage and low voltage during the process of dissolving the fabric. The claim is made that the time required for disintegration and solution is reduced one-half by the use of the current—say from 22 hours to from 8 to 11 on various grades of scrap.

A number of interesting exhibits were prepared by manufacturers of rubber-making machinery and of chemical products used in compounding rubber. The New Jersey Zinc Company had on exhibition its zinc ore from Franklin furnace, and the zinc oxide product which is used as an admixture in rubber articles where toughness is required. Aluminium flake is another trade product used for this purpose. Several producers of natural bitumen and mineral wax also displayed their products, as well as admixtures of these and rubber gum. The effect of these substances is greatly to increase the strength of rubber and to prolong its life. The fertilizer business was represented by the German Potash Syndicate.

Werner & Pfleiderer Company, Saginaw, Mich., showed their apparatus for masticating and washing rubber.

Buffalo Foundry & Machine Company, Buffalo, N. Y., exhibited a vacuum drying apparatus for drying rubber, and also showed their facilities for turning out special iron castings.

C. J. Tagleabue Manufacturing Company, of Brooklyn, N. Y., displayed thermometric and vacuum recorders, in connection with other mechanical exhibits.

J. P. Devine Company, of Buffalo, N. Y., had in operation a commercial vacuum dryer, pump and condenser for the drying of sheet rubber.

Meetings and Papers.

Daily sessions were held for the discussion of chemical and engineering problems connected with the rubber industry. Great interest centered in the subject of standard methods of analysis and standard physical tests. In the matter of specifications for rubber goods, the United States and foreign countries, and several scientific societies were represented by official delegates who hoped to standardize this branch of the industry. Among the other subjects discussed were the possible rubber producers in the temperate zone, and the commercial possibilities of synthetic rubber.

Problems in Vacuum Drying.

The merits of the vacuum drier as a means of removing the last traces of moisture from rubber, were presented by Mr. **J. P. Devine**, of Buffalo, N. Y. From his paper we make the following excerpt:

"My introduction to and connection with the rubber industry was made about ten years ago when I sought to interest manufacturers in this country in a new method of drying rubber. I found, however, that the manufacturer was disposed to be quite satisfied with the then existing method. * * *

"Notwithstanding the discouragements of my early efforts, I made investigation as to methods of drying rubber and learned that little, if any, advancement or improvement had been made up to that time, and this confirmed my opinion of the value of the vacuum process, and I have maintained ever since its introduction that the vacuum drying process and apparatus introduced in Europe by Messrs. Emil Passburg and William Strohn, and in this country by myself, would be and has since proven of inestimable benefit to the rubber industry.

Old Methods and Their Disadvantages.

"For years rubber was dried by any convenient means that would not represent an expenditure of capital, the boiler room, or a room adjacent thereto, serving the purpose until the effects of the elements upon the rubber began to receive attention and study. And then, the improvements consisted largely in the construction of drying lofts, the racks on which the sheeted rubber was hung and the distribution of heat by coils, or by circulation of hot air by means of fans and blowers; little regard however being given to temperature or length of time of the drying process. Until the introduction of the vacuum drying apparatus this primitive method was still in use and occasionally an advocate is still found, who asserts that the hot air method is necessary for the proper curing of some particular grade of rubber. The fallacy of such assertions is proved by the use of the vacuum apparatus drying every grade of crude rubber, and I shall endeavor to make clear to you the claims I make for the superior quality of rubber dried by a properly designed and constructed vacuum apparatus.

"While it is true, considerable thought was given to improve processes for drying rubber, there were no striking departures from the antiquated method of using hot air as the heating medium. The construction of special drying rooms from which direct sunlight was excluded; provisions to eliminate dust and dirt; the regulation of temperatures for various grades of rubber, as well as the attempt to dry the air before being admitted into the drying room, all contributed to avoid the deterioration of the rubber by such means; but the value of these improvements was doubtful as they only tended to reduce the effect of high temperatures with a consequent prolongation of the drying period.

"The fact is that the two insidious enemies of rubber are heat and oxygen and these elements are, and always will be present, and necessarily so, in any system of hot-air drying. They are deteriorating agents and their elimination is most essential for the proper drying of rubber. Their elimination by the vacuum apparatus has proven the superiority of the vacuum-dried rubber in the processes of its manufacture.

"Another and serious objection to the hot-air system of drying rubber is, that rubber as it comes from the washing machine, contains a very large proportion of mechanically bound moisture; while this is readily given off in the hot-air drying room, its expulsion causes a contraction of the rubber, which, with the oxidation constantly taking place, causes a hardening of the surface that prevents the elimination of the last moisture within the rubber, except by a very prolonged drying period, during which time the rubber is further subjected to oxidation and not unlikely to excessive heat. Unless the last traces of moisture are eliminated, 'blowing' is sure to result during the following stages of its manufacture. * * *

Advantages of Vacuum Drying.

"The deteriorating agents—oxygen and excessive heat—can only be eliminated by the vacuum process and apparatus, which afford the proper conditions to dry rubber rapidly, uniformly and thoroughly at a low temperature and without oxidation, independent of climatic conditions.

"It must be borne in mind that under atmospheric conditions a rapid boiling can only take place at 100 deg. C. or 212 deg. F. and that as the temperature decreases, the drying time is extended; while under vacuum, the boiling point is greatly decreased. To illustrate, under a vacuum of 29 in. water boils at 25 deg. C. or 77 deg. F. Rubber dried in the vacuum chamber, while the first free water is being removed, will not be heated practically above the boiling point of water at that particular vacuum; as the moisture is evaporated from the rubber, naturally the temperature of the rubber being dried tends to increase; to prevent any over-heating, the supply of the heating medium—steam or hot water—is regulated accordingly and entirely shut off before the final drying; the last traces of moisture are therefore drawn off by the latent heat in the dryer accelerated by the high vacuum. Because seemingly high temperatures are used at the beginning of the drying process to expedite evaporation, the erroneous impression is sometimes formed that the rubber is overheated in the vacuum chamber; but it must be obvious that in a properly constructed vacuum chamber with its auxiliaries—condenser and pump—properly

balanced, the application of well-known physical laws absolutely prevent any over-heating, if reasonable care is only taken in its operation.

"Then too, the drying process taking place under a high vacuum in the absence of oxygen, oxidation cannot take place. The rubber not being overheated nor impaired by oxidation has greater elasticity and tensile strength, and accomplishes that which is the aim of every manufacturer, to obtain the greatest yield when being made into final product.

"As different grades of rubber must be subjected to varying temperatures, the temperature of the heating medium is easily regulated without over-heating or materially affecting the drying time so that the vacuum process offers many advantages over the old method of drying rubber, whether it be fine Para or Pontianac.

"Another very great advantage of the vacuum process lies in the fact that as the drying period is only a few hours, varying according to grade of rubber, the crude rubber can be washed, dried and processed in a fraction of a day; consequently there can be no deterioration after drying and before using, as it is well known that washed rubber oxidizes very rapidly, and there is no danger of the final manufactured product being porous or spongy due to the presence of moisture. * * *

Financial and Other Economies.

"In an average establishment of today, making a general line of rubber goods, two tons of crude rubber is a conservative estimate of its consumption. If the old hot-air method is used, in order to properly and thoroughly dry the washed and sheeted rubber, six weeks are consumed in the drying process. Seventy-two tons of rubber would be hanging in the drying lofts, which at $1.00 per pound, would represent an idle investment of $144,000 on raw material, the carrying charge alone at 5 per cent amounting to upwards of $20 per day; and should the carrying charges for insurance, factory space, etc., be included, the above sum would be greatly increased.

"The same quantity of rubber could be more thoroughly and permanently dried by one or two vacuum chambers in a day of ten hours, so as to "work up" whatever grade may be required for each day's output and the initial cost of such an installation would be less than the cost of the old-fashioned drying rooms for the same quantity. So that the vacuum chamber pays for itself in the savings on investment, carrying, insurance and other fixed charges on raw material, as well as giving a flexibility to the factory for its daily production that cannot be obtained by any hot-air method.

"To illustrate the great saving in factory space, a vacuum drying chamber having a capacity of approximately two tons of dry sheeted rubber per 10 hours, occupies a space of 8½ ft. high, 15 ft. wide and 9 ft. long, and its auxiliaries, the condenser and the pump, can be conveniently located at any place in the factory in proximity to the dryer.

"In addition, the vacuum drying process offers further advantages over the hot-air system because of the other factory economies derived by its use. The expense for a hot-air system for steam consumption and attendance is enormous. It is an established fact that by any hot-air system not more than one-third of the heat units supplied are utilized in the evaporation of moisture, whereas by the vacuum process practically every heat unit is transmitted to and comes in direct contact with the material being dried. The saving of fuel is consequently most considerable not only on account of shortening the drying time from weeks to hours, but because of the much higher efficiency of the heating medium used in the vacuum drying process.

"The vacuum drying apparatus is constructed of cast iron and is practically indestructible; there are no appreciable maintenance charges and fire hazards are eliminated.

"As to attendance, only one operator is required to operate the vacuum dryer, and while one charge is being dried, he is engaged in filling the second set of trays with rubber for the next charge; and in recharging the apparatus, replaces each tray of dried rubber with one of wet.

Design and Construction of Apparatus.

"A vacuum drying apparatus consists of a vacuum drying chamber which should be constructed of a special grade of close grain homogeneous cast iron equipped with heating shelves made of hydraulically straightened sheet steel plates; I emphasize that the plates should be hydraulically straightened as by this means only can a uniform even and flat surface be secured on which the trays are placed and which will withstand the strain of the varying steam pressures used during the drying process; it is important that the heating shelves are so constructed as to insure an even surface as any distortion of the heating shelves will cause the trays to rest unequal and thereby permit an uneven transmission of the heat to the material being dried.

"Connected with the vacuum chamber is a condenser and it is most important that this auxiliary be of proper condensing capacity for the vapors given out during the drying process. * * * The size and capacity of the dry vacuum pump is of equal importance to the well balancing of a vacuum apparatus, for in order to secure the highest efficiency it is necessary to create the highest obtainable vacuum as quickly as possible and when obtained to maintain a uniform vacuum throughout the drying period.

"Complaints have occasionally been made by some people who have attempted to dry rubber under vacuum, that such vacuum-dried rubber was not satisfactory, and the blame was promptly put on the vacuum drying apparatus and process.

"I may state that though these complaints were, of course, bona-fide, the cause for such complaints was misplaced. The vacuum apparatus and process have the advantage of working almost automatically and require scarcely any attendance, but these advantages have in the above-mentioned cases been abused and of course not without detrimental effects to the vacuum-dried rubber.

"To illustrate what I mean, a certain size of a vacuum apparatus is intended to receive a certain quantity of rubber per charge and naturally the heating surface of the dryer, which is equivalent to its drying capacity, has, as I have stated, to be most carefully calculated for this purpose; and if the instructions for operating such apparatus, which are most simple, will only be followed, I might say it is a physical certainty that the vacuum-dried rubber will be satisfactory and far superior to air-dried rubber because with a vacuum apparatus and process nothing is left to chance or climatic conditions.

"In cases, however, where complaints have arisen, the well-meaning people who were using such a dryer, being surprised at the capacity of the apparatus far exceeding their expectations, thought it right to go a little further by increasing the charge of rubber and ultimately loading the apparatus with a much larger quantity than was intended. Of course, it was soon found out that the increased charge could not be dried in the stated time, nor with the stated temperature of heating steam. As it is only human not to decrease one's desires, the natural human remedy was resorted to, that is, an increased temperature of heating steam and also a prolonged drying time. If you consider that the heating surface at a certain temperature within the dryer is intended for a layer of rubber of a uniform and certain thickness, its capacity, or rather the beneficial results obtained therefrom, will be destroyed or at least impaired by an increased quantity of rubber per charge and an increased temperature of heating steam, because the heating surface itself remains the same and it is this factor which remains constant that upsets the results sought to be obtained by the violation of well known, but not considered, natural laws.

"Experience has taught us to balance the necessary heating surface, to transmit a certain temperature to a certain layer

of material to be dried; and it is a quite erroneous, though common assumption, that the same beneficial results may be obtained from a larger quantity of material by simply increasing the thickness of the drying material and increasing temperature in the belief that the above mentioned factor would increase proportionately. This, however, is not the case, as I will more fully point out.

"If one takes the conductivity of rubber alone into consideration, and the gradual but decreasing evaporation of the water contained therein, it can very easily be understood that by altering some of the factors the physical laws on which our calculations are based will be violated without intention, and the penalty is an unsatisfactorily dried rubber—the cause of which is naturally placed at the wrong door. The fault is not in the apparatus, but in the method of its operation.

"The same remarks refer to the auxiliaries of an apparatus for drying rubber and these auxiliaries consist of a condenser and vacuum pump which are both calculated to correspond with the capacity of the vacuum apparatus they are intended to serve.

"To illustrate what I mean: A vacuum dryer of a certain drying capacity and calculated for a certain purpose is intended to evaporate a certain quantity of water in a given time and of course what is essential, at as high a vacuum as is possible under practical working conditions. All this, is to a great extent, based on practical experience with the very material our apparatus is used for.

"If, however, the condenser, instead of handling the quantity of vapor for which its cooling capacity is calculated, is burdened with ever so much larger a quantity, the result must be detrimental in two ways; it not only reacts on the dryer and the product it is supposed to turn out regardless of time, but also reacts on the working of the pump.

"As regards the vacuum dryer, it is essential to have its inner space continuously freed from the vapor arising from the drying material in order that no inner pressure may be created in such apparatus to lower the vacuum. This can only be done by having the arising vapors taken care of in their entirety during their passage through the condenser, the capacity of which cannot be changed at will.

"If more vapors are created than the condenser is intended for, such vapors will partly remain in the dryer (and create inner pressure); the inner pressure thus created consequently reduces the vacuum in the dryer and in further consequence the boiling point of the water contained in the rubber increases and the rubber will be heated up to a temperature never intended, with detrimental effects to the quality of the rubber. The overcharging, as I said before, affects the efficiency of the pump and prevents it from creating the desired high vacuum. The reason for this is that a dry vacuum pump—the only type in question we have in mind while talking on this subject—is intended, dimensioned and constructed for pumping air and not vapor, particularly as the latter expands so enormously under vacuum. If the pump was intended to exhaust rarified or expanded vapor in addition to rarified or expanded air, its dimensions would be so enormous as to make its use practically impossible.

"If, therefore, the dry vacuum pump has to exhaust vapors which have passed uncondensed through the over-taxed condenser, a burden is placed on the pump for which it was never intended; its work becomes inefficient and most naturally impairs the vacuum and efficiency of the whole installation for drying purposes.

"The use of the vacuum drying process was, of course, first introduced and adopted by the manufacturers to dry washed rubber. In recent years, however, much greater thought and study have been given to the preparation of the crude rubber on the plantation; especially is this noticeable in the quality of the rubber reaching the market from the Malaysian, Straits Settlements, and Congo plantations, where vacuum drying apparatus has been installed and found to be of great value.

"This improved quality of the raw material will not cause the discontinuance of the drying process in the factory. It will, however, tend to restrict the operation for the treatment of such rubber to remove the final percentage of moisture only, and thus simplify factory operation."

Standard Methods of Sampling for Check Analysis.

The Association of American Steel Manufacturers has just adopted a set of rules to be followed in obtaining samples for the check analysis of steel. This latest activity of the association is in response to the need that all manufacturers and many consumers have felt for uniform conditions which should govern both parties when steel is to be analyzed, especially when its *acceptance* or *rejection* depends upon check analyses.

The booklet is entitled "Standard Methods of Sampling for Check Analysis," and it is issued under the new classification of "Manufacturers' Standard Practice" which the Association now uses for certain of its adopted rules, when they are not strictly of the nature of specifications.

In the introduction of the pamphlet it is pointed out to be a recognized fact that the different parts of a piece of steel are likely to vary in composition. This variation occurs principally between the center and the outside, and to a slighter extent is dependent upon the position of the piece in the ingot, and the size of the ingot.

Where a sufficient number of check analyses have been made from drillings properly taken at different points in the heat to represent it fairly, their average has been found to compare favorably with the ladle analysis, which is the analysis of a small test ingot taken at any time during the pouring of the heat.

From this it is evident:

1. That the ladle analysis is more representative of the composition than any single analysis of the finished material.

2. That drillings for check analysis, to be fairly representative, should be taken at a point intermediate between the outside and the center of the cross-section.

3. That a sufficient number of check analyses of different pieces should be made to afford a fair average to compare with the ladle analysis.

1. Points to Be Observed in the Sampling of Material for Check Analysis.

(a) Each heat in a lot shall be considered separately, and pieces for sampling shall be taken to represent the heat as fairly as possible.

(b) Samples must be drillings or chips cut by some machine tool without the application of water, oil or other lubricant, and shall be free from scale, grease, dirt or other foreign substance. If samples are taken by drilling, the size of the drill shall be not less than ½ in. or more than ¾ in. in diameter.

(c) Samples must be uniformly fine and each must be carefully mixed before analysis.

(d) In referring samples to the manufacturer or other analysts for check analysis, a piece of the full-size section, when possible, should be submitted rather than cuttings, unless the latter are specially requested.

(e) Where material has been subjected to heat treatment other than annealing or simple cooling, subsequent to its manufacture, it should be annealed before sampling.

(f) Check analyses are not representative of the original material when its composition has been altered in any way by some operation such as casehardening, overheating, etc.

2. Methods of Obtaining Samples for Check Analysis

Material has been divided into the following classes, depending upon the manner of sampling:

I. MATERIAL SUBJECT TO PHYSICAL REQUIREMENTS.

Samples for check analysis shall be taken from a test specimen. Where it is required to make additional check analyses, samples shall be taken as indicated under II.

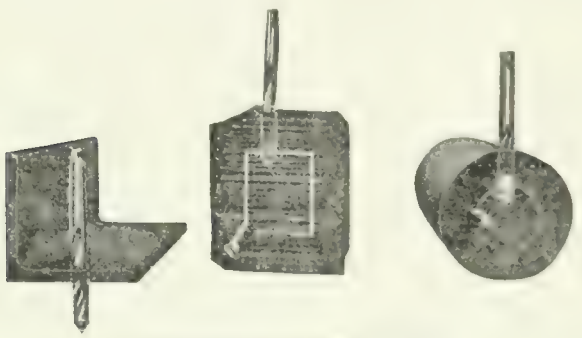
II. MATERIAL NOT SUBJECT TO PHYSICAL REQUIREMENTS.

(*a*) *Special cast, rolled or forged, semi-finished or finished material of large size, such as ingots, blooms, billets, slabs, rounds, shapes, etc., subject to acceptance on check analysis.*

Samples shall be taken at any point midway between the outside and the center by drilling parallel to the axis. In cases where this method is not practicable, a piece may be drilled on the side, but drillings shall not be taken until they represent the portion midway between the outside and the center. See Fig. 1.

(*b*) *Small or thin material, such as plates, shapes, bars, etc., subject to acceptance on check analysis.*

Material for which the previous method is not applicable shall have samples for analysis taken entirely through the material



METHODS OF DRILLING SAMPLES

at a point midway between the outside and the center, or by machining off the entire cross-section.

(*c*) *Commercial material subject to acceptance on ladle analysis.*

The methods described under II (a) and (b) shall apply, except that samples shall be taken at any point one-third of the distance from the outside to the center.

3. Methods of Analysis.

Analyses shall be made by well-known accurate methods. Carbon shall be determined by the combustion method.

4. Rejection of Material on Check Analysis.

Any rejection of material ordered to a specific chemical range shall be based on the following:

(a) The minimum number of samples to be taken from a heat before rejection by the purchaser shall be as follows:

Weight in Gross Tons.	Minimum Number of Samples.
5 or less	3
10 or less but over 5	4
15 or less but over 10	5
Over 15	6

In case the number of pieces in a heat is less than the number of samples given, one sample from each piece shall be considered sufficient.

(b) Separate determinations shall be made on each sample and the results averaged, unless they clearly indicate mixed grades.

The Association of American Steel Manufacturers comprises thirty-two steel manufacturing companies. Mr. A. A. Stevenson is the president; Mr. Jesse J. Shuman, care of Jones & Laughlin Steel Company, Pittsburgh, Pa., is the secretary, from whom copies of the different publications of the Association on Standard Specifications and Standard Practice may be obtained.

The Ohio Copper Company, Bingham, Utah, has issued a statement of operations covering the period from October, 1911 to March, 1912. The copper content of the crude ore was 1.176 per cent, and of the concentrate 22.179 per cent. The ratio of concentration was 33.74:1, and the quantity treated was 311,067 tons. The loss in concentration was 44.13 per cent.

Convention of Foundrymen's Association and Institute of Metals.

The allied foundry interests of the United States convened in annual session in Buffalo, N. Y., September 24 to 27, 1912, to consider the past year's progress in the metal founding industry. The ever growing importance of this branch of metallurgy was again indicated by the very large attendance and the number of interesting and important papers presented.

Three different organizations were in session: The American Foundrymen's Association, The American Institute of Metals, and The Associated Foundry Foremen. All joined in an opening meeting on September 24th, presided over by Mr. Joseph T. Speer, president of the American Foundrymen's Association. Addresses of welcome were made by Mayor Fuhrman, of Buffalo, and by the president of the Chamber of Commerce. Response on behalf of the visitors was made by Mr. A. E. Howell, of Nashville, Tenn., one of the vice-presidents of the Association.

Entertainment

On Tuesday morning a visit to the Roycroft Shops, with dinner at the Roycroft Inn, was arranged for the ladies. In the evening the Associated Foundry Foremen held their annual banquet while the ladies attended a theater party. A boat ride in the harbor and down Niagara river was given on Wednesday morning.

The entertainment of Thursday comprised a sight-seeing automobile tour of Buffalo, in the morning, and a subscription dinner at Hotel Statler in the evening. Secretary Nagel, of the Department of Commerce and Labor, and Elbert Hubbard were among the speakers at the banquet.

The annual display of the Foundry and Machine Exhibition Company was open daily to visitors at the Broadway Arsenal, Buffalo's new exposition building. It was again a brilliant success.

In the following we give abstracts of two papers presented. Further abstracts are reserved for our next issue.

The Electric Furnace for Brass Melting.

A paper on this subject was presented by **Mr. G. H. Clamer** and **Dr. Carl Hering,** of Philadelphia, Pa.

The paper summarizes the advantages of the electric over the fuel furnaces for brass melting and points out the incorrectness of the prevailing belief that owing to the necessarily greater cost of electric over fuel heat, it would not pay to use electric heat for such a low melting alloy as brass. After giving a table of the cost of a kilowatt-hour of heat from electric energy, water power, wood, coke, oil and coal, assuming perfect conversion, the authors show that although the discrepancy between this cost of electric and fuel heat is great, there are many other factors of money value which more than balance this difference.

One is the far greater efficiency, that of the oil furnace being only about 10 per cent and that of the electric from 65 to 75 per cent. In fact it would take less oil to operate an oil engine, generate electric energy with it and use this in a furnace than to melt the metal directly with oil. Moreover there is no oxidation, no combination with sulphur from coke gases, less volatilization of zinc, sharper and less faulty castings, less trouble and loss in running together finely divided scrap metal. It is shown that the saving of metal alone, amounting to probably about 20 cents per 100 lb., more than pays for the electric energy, besides saving the cost of the oil or coal and the crucibles. The authors favor the combination of preheating with fuel heat and supplying only the higher temperature heat electrically.

A table gives the kw-hours required for melting and superheating 100 lb. of various metals and alloys, assuming no losses.

The various types of electric furnaces available for brass are discussed briefly and their advantages and disadvantages pointed

out, more particularly the resistance furnace with which the authors have experimented and which they are developing. In this (the so-called "pinch effect furnace") the heat is generated in a small portion of the liquid metal which is then immediately forced out into the bath in the hearth; cold metal is melted by immersion. The heat is generated in the metal itself, where it is wanted, hence at high efficiency; it can be forced to a high degree whereby the size of furnace for a given output is increased. The systematic forced upward circulation brings all suspended impurities to the top, hence purifies the metal. Being a closed form of hearth the loss of zinc will be very slight. A moderately large furnace of this type for bronze melting is under construction and is expected to be in commercial operation very soon.

The authors are of the opinion that melting brass in a suitable electric furnace is not only not more expensive, but will actually be cheaper when all factors, including the smaller loss of metal, are taken into consideration.

Electric Melting for Copper and Brass.

Another interesting paper on the use of the electric furnace in the copper and brass industry was presented by Mr. **C. A. Hansen,** of the General Electric Company, Schenectady, N. Y. In the first part of the paper figures are given on the performance of three commercial oil furnaces, which he then compares with the use of the electric furnace.

Experiments on the electric melting of copper were made in a furnace, designed by Mr. C. A. Weeks, of Philadelphia, Pa., primarily for the distillation of zinc. From the results of the tests the author figures the power required to melt copper after the furnace had been warmed up. Two different methods of reasoning lead to 298 and 243 kw-hours per ton of copper respectively corresponding to efficiencies of 65 and 80 per cent.

The oil burned in an oil-fired furnace would, if burned in a modern oil engine, supply more than enough electrical energy to melt the same amount of metal in the electric furnace.

With respect to fuel and energy cost the following comparison is made: With oil at 2.5 cents per gallon, power on a 3-heat, 12,000-lb. per day output will have to sell between 0.40 cents and 0.82 cents per kw-hour to equal actual costs of oil and blast in oil-fired furnaces where energy to the blower is supplied at the very nominal rate of 1 cent per kw-hour and where 1.78 to 3.46 gal. of oil are used in melting 100 lb. of averaged red brass.

Even the lower figure, 0.40 cent per kw-hour, is guaranteed by some of the oil engine concerns selling engines of the capacity necessary to operate a 2-ton furnace, contingent on 2.5 sents per gallon.

The higher figure, 0.82 cent per kw-hour, is obtainable for day loads from a great many of the central stations in the various cities in this country. The electric melting of brass and copper is, therefore, on a more attractive basis as regards energy costs than is the electric melting of steel and the latter undoubtedly has a wide commercial application for castings.

As to the loss of metal "it is certain that if equally careful crews operate electric furnaces and oil-fired furnaces the former will have a decided advantage."

Theoretically, the electric furnace has an immense advantage over the ordinary oil-fired furnace, in that the electric furnace may be practically sealed to prevent access of air—which means that so long as the vapor pressure of the zinc in the charge does not exceed atmospheric pressure the maximum possible loss of zinc must be the furnace full of zinc vapor.

The author finally compares briefly the relative advantages and disadvantages of the induction furnace, the direct arc furnace, the indirect arc furnace, and the resistance furnace for the special purpose of brass melting.

On account of limitations of space, further notes on the two papers, abstracted above, as well as on quite a number of other interesting papers must be reserved for our next issue.

Non-Ferrous Metal Market.

With the exception of copper, the price of all the principal non-ferrous metals has appreciated materially during the last month. There has been a decided advance in lead and a strong upward tendency in tin and spelter. The domestic tin market has not kept pace with the bull speculation in Europe, but it is expected that prices may go still higher. Consumption of all the metals is fairly good.

Copper.—There has been no special feature in this market. Electrolytic has sold freely and Lake has been in moderate demand, but sellers show no anxiety to push sales. The last New York quotations are: 17⅝@17¾ cents for Lake and 17.45 @17.50 cents for electrolytic.

Tin.—This market has reflected European operations and has shown great strength, reaching nearly 50 cents on September 16. The latest reports give a price of 48¾ cents for September delivery.

Lead.—On Sept. 9 the principal producer raised the price to 5.10 cents and demand has continued good. The metal is regarded as holding a strong position. Price at New York is 5.10 cents, and at St. Louis, 4.95@5 cents.

Spelter.—A fair business has been done at advancing prices, but importations have already been made which have had the effect of checking a further rise and placing New York quotations below their parity with St. Louis. The last quotations are 7.45@7.55 cents New York, and 7.35@7.45 cents, St. Louis.

Other Metals.—Business in aluminium continues good with prices firm at 24¾@25 cents, New York. The antimony market has improved and quotations range from 8⅛ to 8¾ cents for various grades. Quicksilver is steady at $42 per flask of 75 lb. New York, and $41.50 San Francisco.

Personal.

Mr. James F. Callbreath, secretary of the American Mining Congress, is at Spokane completing arrangements for the annual convention which will be held November 25 to 30.

Dr. Joseph A. Holmes, director of the Bureau of Mines, will be one of the principal speakers at the American Mining Congress in Spokane, November 25 to 30.

Mr. George F. Comstock, metallographist with the Park works of the Crucible Steel Co., Pittsburgh, has resigned to take charge of the new physical testing laboratory recently erected at a cost of $10,000 by the Titanium Alloy Mfg. Co., at Niagara Falls, N. Y.

Mr. Charles Vickers, editor of the non-ferrous casting department of the Foundry, has resigned to take charge of introduction of copper-titanium for the Titanium Alloy Mfg. Co., Niagara Falls, N. Y.

Mr. B. Magnus, general superintendent of the Electrolytic Smelting & Refining Co., Port Kemble, Australia, has been appointed general manager for the Mt. Morgan Gold Mining Co., of Queensland. He will continue to act as consulting engineer for the refining company, which treats all the blister copper from the Mt. Lyell and Mt. Morgan mines.

Mr. A. W. Cole has taken a position as mill superintendent with the Concheno Mining Co., at Temosachic, Chihuahua, Mexico.

Mr. A. F. Flynt, metallurgist, of Tepic, Mexico, is traveling in the United States.

Prof. R. C. Benner, of the Department of Industrial Chemistry in the University of Pittsburgh, spent part of the summer vacation in Ontario.

Mr. R. B. Watson, manager for the Nipissing Mines, of Cobalt, Ontario, Canada, is in Germany taking baths for the relief of rheumatism. During his absence **Mr. Hugh Park** is in charge of operations.

Mr. Bernard McDonald has returned to Los Angeles from a trip to the Cobalt district. He is making his home temporarily in Los Angeles during the Mexican troubles.

Mr. E. M. Hamilton is at Cobalt, engaged in completing the new Nipissing mill which will shortly be put in commission.

Mr. Walter Douglas, who was reported captured by Mexican rebels in Sonora, is now known to have escaped to Agua Prieta, using a railroad motor velocipede.

Mr. Paul W. Webster has resigned his position with the M. H. Treadwell interests, and after October 1 will devote his time to the business of the Lutz-Webster Engineering Co., which he has formed with **Mr. William H. Lutz.** The new company is an incorporation of the Grays Ferry Machine Co., Philadelphia, and will continue the same line of work at the same address, 3103 Grays Ferry Road.

Obituary.

Mr. T. Lane Carter died on September 3, in Montana, as the result of injuries received while examining the Polaris mine. Mr. Carter entered active engineering in South Africa, where he was on the staff of the Crown Deep and Robinson Central Deep mines. He had spent several years in foreign lands, engaged in the practice of his profession, and was a contributor of timely articles to the technical press. Mr. Carter was married just a few months prior to his death.

Mr. S. C. Hazleton, superintendent of the Midvale smelter of the United States Smelting Co., Utah, was killed in an automobile accident near Salt Lake City on the evening of September 6. The car in which Mr. Hazleton was riding was struck by a street car while trying to avoid a collision with a carriage. Mr. Hazleton was about 35 years of age and unmarried. Coming to Utah a few years ago, he first took charge of the Murray plant of the American Smelting & Refining Co., going later to his present position.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (*Continued*).

597,820, Jan. 25, 1898, Nathaniel S. Keith, of Chester, England.

Relates to obtaining gold and silver from ores or materials containing the same. The apparatus consists of an upper tank containing ore to be treated, an intermediate electrolytic cell and the lower tank to receive the solution from the cell. The ore is treated with a solution, which is then electrolyzed and then run off and pumped back onto the ore again. The process is as follows: To a solution of cyanide of potassium varying from 0.01 per cent to 5.0 per cent in strength, a solution of mercury is added in a solution of cyanid of potassium, for instance oxid of mercury in a solution of cyanid of potassium. The solution of mercury is added preferably in quantity sufficient to supply an ounce of mercury to each ounce of gold to be dissolved. Having prepared the solution, the gold- or silver-bearing materials are submitted to its action in the same manner as practiced in vats or tanks. In a solution of cyanid of potassium, gold is electropositive to mercury and is capable of combination with the equivalent acid constitutent of mercury associated with the solution of cyanid of potassium. The gold thus becomes much more freely soluble in the cyanid of potassium solution. It is necessary, in order to insure speedy dissolving of gold by a solution of cyanid of potassium, to have the particles of gold in contact with some material electronegative to it in that solution. Besides mercury, iron and carbon both possess this quality. In the case of iron, it is used in solution, as just described when mercury is used. If carbon be used, it is mixed in a pulverized or other finely-divided state with rocks or ores likewise finely pulverized or divided so that the particles of carbon may be more rapidly brought into contact with the particles of gold or silver. When the solution is drawn from the vats it is passed through an electrolytic cell continuously, so that the solution entering the vat runs out at another place, exhausted of its gold and silver constituents, into another vat containing gold- or silver-bearing materials. For the anode, zinc or iron in the form of plates is used. The surfaces of the zinc are preferably amalgamated. Mercury may also be used as an anode. Two kinds of electrolytes are used, one for the anode and one for the cathode. When zinc is the anode a half saturated solution of chlorid of ammonium in water or a like solution of sulfate of ammonium is used for the electrolyte for either zinc iron or carbon anode. When mercury is the anode a strong solution of cyanid of potassium is preferably used. For the other electrolyte is used the solution containing the gold or silver or both and the gold is deposited upon a copper cathode which has its surface amalgamated.

598,193, Feb. 1, 1898, Emile Andreoli, of London, England.

Relates to the electrodeposition of gold or silver or other metals from cyanid-compound solutions. Peroxidized-lead plates, as anodes and zinc cathodes are preferably used. A cyanid of gold and potassium, or of silver and potassium solution, is not contaminated by metallic salts and remains limpid when peroxidized with lead anodes. The anodes and cathodes are perforated, disposed transversely in a tank, and the gold solution, entering at one end of the electrolyzer, passes through the holes of the electrodes in perfect contact with the surface of the cathodes on which the gold is deposited. The solution flows out through convenient outlets at the other end of the tank.

600,351, March 8, 1898, Edgar Arthur Ashcroft, of Melbourne, Victoria.

Relates to the treatment of ores and products containing copper, iron, and zinc; and refers to patent 546,873, which this process resembles; with the exception that for the iron anodes (either entirely or partially), anodes consisting of the iron, copper-bearing mattes, regulus or crude metal are substituted. The apparatus consists of a mixing tank, consisting of an open tank containing a stirrer, in which the finely-pulverized roasted ores are placed with a leaching solution containing a ferric salt. The leaching is continued for from one-half to two hours, according to the composition of the ore. The greater part of the zinc and a small quantity of any other metals present is extracted. The solution is filtered off, and the residue is fit for smelting as usual. The solution is electrolyzed in divided cells, the diaphragm preventing intermingling of anolyte and catholyte, the zinc solution entering the cathode compartments of a succession of cells, wherein the zinc is deposited; the solution is constantly circulated from the cathode compartments of all the cells, to the anode compartments of the first cell containing a soluble iron anode; from there it goes to the anode compartment of a succeeding cell containing a carbon anode, in which the iron solution is oxidized, so as to render it fit for use again in a subsequent leaching operation.

601,068, March 22, 1898, Frederick W. Whitridge, of New York, N. Y., Administrator of Ernst Werner von Siemens, deceased.

Relates to the method of and apparatus for extracting gold from its ores, residues and tailings. A vessel of any approved form has a grating a short distance above its bottom and a perforated plate resting on the grating. The broken ore is laid on the plate in a thin layer and is covered with a weak solu-

tion of cyanid of potassium of from 0.05 per cent to 0.13 per cent. Perforated air pipes are placed in the bottom of the vessel under the grating. Air or oxygen, or ozone, is forced through the pipes. The liquid is agitated above the ore and the air is forced upward through the ore simultaneously. The ore is treated from four to six times over with the cyanid solution, and each treatment lasts from five to six hours, so that all the gold may be dissolved out of the ore. The gold depositing-vessel is separated into compartments by partitions, each alternate partition being provided with an opening at its lower part. The gold solution is conducted into the vessel through a pipe and is caused to circulate continuously through the compartments by any means, such as a pump. The gold solution is subjected to electrolysis while circulating in the vessel. The anodes are of iron and the cathodes are of lead. The electricity is suplied from 3.5 to 4 volts and a current of from 0.5 to 1.5 amp per square meter of surface of cathodes. The lead cathodes containing from 2 to 12 per cent of gold are removed from the cell periodically and smelted. By repeatedly forcing air through the solution in the vessel and agitating it, the gold can be dissolved by a weaker solution than heretofore used.

603,904, May 10, 1898, Joseph R. Hebaus, of Butte, Mont., assignor of one-half to Frederick P. Conroy, of same place.

Relates to an apparatus for extracting precious metals from ores, tailings and other compounds. A tank has a lining of amalgamated copper which constitutes the cathode. Agitators having arms radially extended, of iron, constitute the anode. By a sun-and-planet motion, the agitators revolve on their axes and travel around the tank to thoroughly stir its contents. In the operation, the tank is charged with water and the agitators set in motion. The ore is pulverized, introduced gradually, and then is gradually added salt, caustic soda, lime, or other alkaline earths. Ores which carry but little silver do not require salt. Ores which carry silver in quantity require 1 lb. of salt to the ounce of silver. To 1 lb. of caustic soda, 16 lb. of lime are used. The charge is now ready to receive the chemical solution, which consists of from one-fourth to three-fourths per cent of cyanid of potassium, and the electric current turned on. Diluted bromin and sodium dioxid are added during the operation, care being taken to have the potassium cyanid in excess and not to add the bromin and sodium dioxid faster than the cyanogen is set free. After treatment of from 2 to 3 hours, the ore and solution are drawn off.

BOOK REVIEWS.

A Text-Book of Inorganic Chemistry. By **G. Senter,** D.Sc., Ph.D. 4½ x 7½ in. (11½ x 18 cm.). 583 pages, 90 illustrations. Price, $1.75 net. New York: D. Van Nostrand Company.

A well-written book, based on the fundamentally correct principle that "a study of the facts on which laws and theories are based should precede the statement of the laws and theories themselves." Under "Steel," p. 538, *wrought* iron is mentioned instead of *cast* iron—an oversight. The book is well printed, on good paper, and is sold at a low price.

Notes on Qualitative Analysis. By **Horace G. Byers,** Professor of Chemistry, University of Washington, and **Henry G. Knight,** Director of Experiment Station, University of Wyoming. 8vo., 181 pages, no illustrations; price $1.50 net. New York; D. Van Nostrand Company.

The authors apologize in the preface for publishing a new text-book on this subject; the reasons they submit are satisfactory to themselves, but not above discussion. The best reason given is that they are confronted with a special environment, and use qualitative analysis principally as an experimental illustration of the chemistry of the metals and to develop laboratory technique. The book is published "chiefly for home consumption." The equations are written in a somewhat intricate manner, which is matched by the complex explanations put forward. Instead of saying, for instance, that Ag Cl is found, by experiment, to be soluble in ammonia, a long explanation is given as to *why* it ionizes and so passes into solution; this, according to the reviewer's viewpoint, is putting hypothesis ahead of observation, and teaching in exactly the reverse of the rational manner.

Handbuch der Materialenkunde für den Maschinebau. By **Dr. Ing. A. Martens. Part II:** Die technisch wichtigen Eigenschaften der Metalle und Legierungen. By **E. Heyn. Section A:** Die wissenschaftlichen Grundlager für das Stadium der Mettalle und Legierungen. Metallographie. Royal octavo, 19 x 27 cm., 506 pages, 489 illustrations, 19 plates. Price, bound, 42 marks (price in New York, $11.20 net). Berlin: Julius Springer.

Another monumental work, such as German skill and patience alone can produce. With something like majesty the treatment moves systematically through the following chapters: General properties of metals and alloys, the phenomena of setting and cooling alloys, cooling curves. Structures of metals and alloys, Methods of investigation, Mechanical properties and hardness, Metals and gases, Shrinkage, blowholes and segregation, Fluidity, Magnetic properties, Electrical conductivity. Each of these chapters is a treatise in itself, systematically divided into A, B, C, etc., subdivided into 1, 2, 3, etc., and these headed *a, b, y,* etc. The amount of information is so great as to defy abstracting or even cataloging. The manner of treatment, however, deserves noting. It is clear, exact and wherever possible *quantitative.* On the most obscure questions the actual figures are given whenever they exist. The result is highly satisfactory to the searcher for information; he feels that here, at last, are the actual data so far as known. Two rather glaring omissions must be noted: Vapor tensions of metals and alloys; heat conductivity. They are not mentioned. We hope they will be considered in Section B.

Every investigator of metals and alloys who can read German should add this book to his working library.

Elektrometallurgie, von **Dr. Friedr. Regelsberger. Ten by** fifteen centimeters. 140 pages, 16 illustrations. Bound in cloth. Price, 80 pfennigs. (Retail price in New York, 30 cents.) Leipzig: G. J. Göschen.

A carefully written review of the field of electrometallurgy, attractively printed and bound, and sold for nearly nothing. It might be difficult to convince American publishers that the Göschen establishment is not a philanthropic institution; with money to give away.

The writer divides the book into two parts: general electrometallurgy, describing the classification of processes, and special electrometallurgy, describing the details of application to the various metals. The division of the first part is clear-cut and practical: (I) electrolytic decomposition of aqueous or similar solutions; (II) electrolysis of melted salts (free from water), or pyroelectrolysis, and (III) pure electrothermal or electric furnace processes, in which electrolysis is absent.

There is very little to criticise in the book; Heroult is not given credit for his work in obtaining aluminium, nor is Gerod mentioned in connection with electric furnace steel. In truth, however, it is not a mere "pot-boiler," but a carefully written book by a competent scientist.

Cours de Métallurgie des Métaux autres que le Fer. Par **Eug. Prost,** Professeur à l'Université de Liége. 88 pages, 483 illustrations. Price, bound in cloth, 30 francs. Paris and Liege: Librarie Polytechnique, Ch. Beranger.

The metals treated are zinc (150 pages), cadmium (6,) lead (126), silver (92), gold (86), copper (178), nickel (33), cobalt (6), tin (40), mercury (24), antimony (18), bismuth (13), aluminum (29), platinum (9), manganese (9), chromium (8), tungsten (7), molybdenum (6), titanium (6), vanadium (10).

Considering that the book is all the work of one man, it is very well-written, American practice being exceptionally well represented for a foreign book, but this is really too large a field to be treated properly in this way. Two hundred and fifty years ago we passed the date at which a well-educated man could know practically all known sciences, and with the advent of the Twentieth Century we have passed the limit at which one man can know all metallurgy. To know well the metallurgy of iron and steel alone, is heavy work for any one man, and for one person to know well the metallurgy of all the non-ferrous metals is a doubtful possibility. As a consequence of these conditions, an expert in each of the metals treated of in this book can find mistakes and omissions, although in the main the information given is complete and reliable. We cannot understand why sodium, calcium and magnesium are omitted entirely.

As a matter of fact, if such a compilation is needed, it should be written in parts, each by an expert in his own line. If Mr. Ingalls were to condense the important principles and facts of the metallurgy of zinc and cadmium into 156 pages, and Prof. Hoffman similarly treat lead in 126 pages, Dr. Peter's copper in 178 pages, etc., a *vade mecum* for the metallurgical student would result which would be as free from errors and as complete as could be produced. But why refer to something non-existent and probably non-obtainable? We have Prof. Prost's book. As the product of one brain and hand it is nearly as good as could be expected; it is more up-to-date than Schnabel's Handbook, but not quite so generally accurate, and it is probable that many people will find it of considerable use and service, particularly metallurgical students.

Traité de Métallographie. Par **Félix Robin.** 464 pages, 244 illustrations in text, 460 reproductions of microphotographs. Paris: A. Hermann.

Though as a systematized branch of knowledge dating only from 1895, the present status of metallography is indicated by this voluminous treatise, which comprises about 450 large octavo pages, 244 illustrations in the text, and no less than 460 reproductions of microphotographs. While reposing largely on the microscopic examination of polished sections and surfaces after corrosive treatment of various kinds, the science as here presented also relates to physical examination in general, including the investigation of the nature of the electric spark drawn from a specimen, the effect of an electric arc on a polished surface, the determination of thermal and electrical conductivity, and of the magnetic properties.

The heads of the various chapters of the book are as follows: Generalities and methods, preparation of specimens, methods of examination, constituents, diagrams, qualitative analysis, general constitution of metals, study of the principal constituents of alloys, quantitative analysis of steel, copper, lead, zinc, tin, nickel, manganese, aluminium and precious-metal alloys, physical state and disposition of elements, slags, precipitates and powders.

A section of the first chapter has, the author states, the purpose to encourage the general industrial adoption of metallographic analysis, and to this end there is given an account of the material service which the new science can render to a long list of metal industries. A neighboring section gives a sketch of the development of metallography from Sorby, who in 1864 was ridiculed for proposing the microscopic examination of rail sections, to Osmond, whose capital work dates from about 1895. The author omits reference to his own contributions, but in a preface Osmond points out their extent and value, and foot-notes throughout the book give credit and bibliographical references to the work of other laborers in the field.

The treatise is essentially practical in nature, the innumerable methods of examination, analysis, etc., being presented in such form as to give the work the character of a comprehensive handbook.

Industrial Depressions. By **Geo. H. Hull.** 6 x 9 in., 287 pages; price, $2.75 net. New York: Frederick A. Stokes Company.

An analysis of the causes of such depressions, a classification of the same, an attempt to provide a remedy for such as result from industrial derangements, and a defence of the thesis that "iron is the barometer of trade."

The thesis is not new, but it is brought out in a new way and proved from a new angle. The statement that "overproduction" is a misnomer, and should be called "temporary surplus production," is skillfully defended as an incident of the struggle to bring "regularity of supply out of irregularity of production."

The principal cause of the fluctuations in question, however, is found by the author to be the large volume of *extra* or *optional construction* entered into by the inducement of low prices at the low point of a depression. These contracts bring about a revival of business, an increase in the agencies of production, and then the down grade into the slough of the next depression as soon as these temporary or emergency contracts are filled.

The remedy proposed is for the government to publish monthly all pertinent information in relation to construction under contract and producing power to meet these contracts, so as to forecast accurately the trend of business and the trend of prices.

The analysis is clever, but the remedy proposed appears inadequate. In any case, all persons interested in studying industrial economics will find the book readable, interesting and stimulating to thought.

Handbook for Ironfounders. 3¾ x 6½ inches, 155 pages. Issued by the Frodair Iron & Steel Company, London.

This little handbook deserves notice; it has such an "antique flavour." It contains much reliable information gleaned from experience, and much unreliable information gathered from inexperience and culled from second and third-class books. It is the opposite of clear and scientific; it is usually muddy and scorns exact science. Some of its statements are the opposite of "practical," and others are "gems" in their way. For instance, where is hard-headed common sense to be found in this statement:

> "What the foundryman wants from the cupola at the tap-hole is an iron hot and fluid enough to make a sound casting, regardless of the amount of fuel required to produce it."

Or, consider the mental force behind this:

> "It is not the velocity at which the blast passes into the cupola that drives it to the center, but the force behind the blast."

Or, ponder on the wealth of information in this:

> "Iron cannot be melted hot and fast in a cupola with either too much or too little fuel, and foundrymen have only to melt their iron as hot and fast as it can be melted in a cupola of the size they are using to know that they are not using either too much or too little fuel in melting."

In order to give honor where honor is due, let us say that the above expressions originated with Mr. E. Kirk in his book on "The Cupola Furnace," and are quoted by the technical staff of the Frodair company as nuggets of metallurgical wisdom!

Where the Frodair experts have their own say, however, they have expressed some very commendable ideas. Their hints on cupola practice and blowing machines are good, and the ten pages on the futility of expecting good castings when adding steel to cast iron in the cupola contain very timely and valuable advice. Their data must be taken, however, wherever it professes to be exact, with several grains of salt, *e. g.*, cast iron flowing from a cupola at a "yellow colour" is said to be at 996 deg. C.!

The book smacks of medievalism, and leans toward prejudice instead of scientific progressiveness.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Vol. X — New York, November, 1912. — No. 11

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

J. W. Richards, Ph.D., President.
James H. McGraw, Vice-President.
Curtis E. Whittlesey, Treasurer. E. F. Roeber, Secretary.

239 West 39th Street, New York.

Achievements and Problems in Fertilizer Chemistry.

An indication of the marvelous rate at which the commercial importance of the artificial fertilizer industry is increasing from year to year, is the equally marvelous increase of chemical research activity now centered on problems of fertilizer chemistry. In our last few issues we published quite a number of interesting papers presented before the International Congress of Applied Chemistry reflecting both achievements and hopes of energetic workers in this field.

The three papers by Dr. Eyde, Dr. Bernthsen, and Dr. Palmaer, which were published in our issue of September 12th, reported actual achievements. Dr. Eyde's paper on the engineering and commercial success of the Baekeland-Eyde process for making nitrates from atmospheric nitrogen was a wonderful story of the creation of a new and very important Norwegian industry, built up by Norwegians and limited to Norway and such other countries as are favored in an equal way with exceedingly cheap abundant hydroelectric power. The product is calcium nitrate or "Norsk saltpeter."

Dr. Bernthsen's paper was an equally wonderful story, how through German energy the synthesis of ammonia has been accomplished. The Badische Company has sold out to Dr. Eyde its interest in the Norwegian nitrate works and is concentrating its efforts on ammonia. From the nature of the process its application is hardly limited to any country.

Dr. Palmaer's interesting paper on his method of producing bicalcic phosphate fertilizers with the aid of electrically produced acid and alkali also records an accomplished fact since the process is in commercial operation in Trollhattan, Sweden. The process would seem to have promising prospects on this side of the Atlantic especially for the phosphate deposits in Canada and in Virginia.

In the present issue we publish a series of congress papers all written by American chemists and all dealing with the burning problem of the possibilities of an American potash industry. The object is to get independent of the German potash monopoly. There are many possibilities, but most of the papers record chiefly the hopes of the inventors. Undoubtedly Dr. Cushman has gone furthest in his large-scale experiments. What has so far been accomplished is certainly encouraging, and the object is worth the work that is spent on it.

"Juicing In."

In any new art or in any new science, it is of considerable importance to have framed up a new set of words, precise and definite in their meaning, to apply to new forms of apparatus and operations or reactions. The scientific world owes a no mean debt to Michael Faraday for his foresight in asking the advice of an eminent philologist and making fit the terms electrode and ion, anode and anion, cathode and cation, diamagnetic and paramagnetic. These words are definite and by their

derivation connote their own particular functions and properties. These words have been invaluable to the cause of science.

It seems now apropos to discuss some new terms for two operations of the electric smelting furnace. When an electric furnace is started up for the first time it seems disconcerting to say that the furnace is "blown in." The electric furnace engineer is entitled to his own jargon and in actual practice we have heard him avail himself of the term so familiar to all classes of the electrical world, "juice," and coin the verb "juice in" or "juice on." Thus it might be said that the U. S. Steel Corporation "juiced in" its first Heroult furnace in 1909.

When a coal or coke furnace is "banked" or "on dead fire" it is kept at a heat by a gentle blast slightly below the operating temperature in a condition ready to be started again, when desired. Similarly another phrase might be coined and an electric furnace said to be "on dead-juice" when it is kept by the use of a small amount of electrical energy in a constant available metallurgical condition.

These terms have been used in actual practice; they are proposed here tentatively as to their availability for more general use and we wish that our readers who can, would give the electrometallurgical world through our columns any suggestions and comments on this subject of practical nomenclature.

San Francisco, 1915.

All the national engineering and scientific societies are likely to decide to hold a meeting in San Francisco at one or the other time in 1915 during the Panama-Pacific Exposition. This will be very gratifying as it will permit an almost unprecedented opportunity for an exchange of ideas, if properly organized. But if this organization is not perfected long in advance, these meetings are likely to be held, as we said, "at one or the other time" of the year. This is the point to which we wish emphatically to draw the attention of those interested in the success of the meetings to come.

The two largest congresses in course of organization and of especial interest to our readers are the International Engineering Congress and the International Electrical Congress. The International Engineering Congress is being organized under the auspices of the American Society of Civil Engineers, the American Institute of Mining Engineers, the American Society of Mechanical Engineers, the American Institute of Electrical Engineers, and the American Society of Naval Architects and Marine Engineers. This is perhaps "representative" enough, although we do not think so, chemistry being wholly unrepresented. An International Engineering Congress to become a real success should be organized on the broadest possible foundation. But this is aside the point we wish to make here.

The organization of the International Electrical Congress is well under way and it is hoped to make it a worthy successor of the congress held at the time of the St. Louis World's Fair in 1904. The fear has been expressed that one of the two congresses might overshadow the other, and that the result would be detrimental to both. This will certainly be the case if on account of the fear of being overshadowed the decision should be reached to hold the two congresses at different times of the season, as this would necessarily impair the attendance at one or the other occasion or both.

The chemical societies have not yet made any arrangements for 1915 with the exception of the American Electrochemical Society which has accepted in principle, through its Board of Directors, an invitation to meet in San Francisco in 1915. But, of course, no date has yet been fixed. It will be logical for the American Electrochemical Society to meet jointly or at least simultaneously with one of the above named big congresses. But which one should they choose if the congresses were held at dates far apart? In the same dilemma many other individuals and societies would be found.

Clearly this matter of fixing the dates is of first importance for the final success and those responsible for the reorganization of the two congresses should decide to come together as soon as possible. It will not be necessary to set exactly the same dates for the two congresses. They may be made to overlap or to follow each other, but in fixing the dates the interrelated interests of all must be taken into account.

Past experience proves that it is not too early now to have the importance of this matter properly fixed in the minds of those who will be held responsible in 1915.

Modification of Vacuum Filtration

The records of the Patent Office usually are dry, prosaic and matter-of-fact, and unlikely to be of broad general interest. And yet, when regularly perused over a long period of time, they reveal peculiar qualities of human nature. To illustrate: Let any inventor conceive an original, fundamental idea, and make it public through the Patent Office. Straightway, a score of modifications of the invention will appear, perhaps showing improvement in some detail which did not occur to the original inventor, but more particularly revealing the variety of forms which the same suggestion will assume in different minds. The record tells a story of a few original conceptions and many modifications or adaptations; of a few minds that did the suggesting and of many more which needed the merest hint in order to bring out a dormant idea. It would be unfair to assume that the latter class are only copiers, for often their modifications carry the original idea to a more logical conclusion, and give it a more useful form.

Since Moore first applied a vacuum to the filtration of ore-slime in the cyanide process, numerous changes have been proposed in the form of apparatus embodying the invention. Some of these have been eminently successful because they met conditions which were not anticipated by the original inventor; others have not yet had an opportunity to prove their worth. Moore's unit was a number of leaf filters which he moved from tank to tank in order to go through the cycle of filtration. This was modified by Butters who kept the filters stationary and pumped the various solutions to and from the filter tank. Ridgway went a step further, making a continuous process by causing the units to travel in a circular path through a succession of tanks containing the different solutions. Thus we find at least three modifications of the "basket" type of vacuum filter.

Later we find a different modification in which the filtering surface is placed on the peripheral surface of a large drum, giving the continuous "drum" type of filter as in the Oliver and Portland. This form has also been modified by a proposal to filter from both the outer and inner surfaces of the drum.

The horizontal table type is still another modification which, however, has not yet been widely used. Caldecott has applied

the principle to dewatering sand, and several American metallurgists have embodied the idea in machines for slime filtration. In this form the filter units are arranged as segments in a revolving round table, giving continuous operation as in the drum machines.

Recently the patent records have disclosed a new modification which for want of a better designation might be described as the "wheel" type of filter. One of these was noted in our last issue, and two more are described in our columns this month. Essentially this type is a series of wheels mounted on a shaft, and revolving in a tank such as is used with the drum filters. The filtering members are leaves placed between the spokes of the wheel as in the horizontal table type. In one case the inventor proposes to perform the several operations of a cycle by pumping the different solutions to and from the filter box while the leaves revolve through it making a sort of continuous Butters filter. In another the characteristics of the Moore are retained.

Thus the variety of vacuum filters is almost kaleidoscopic, and yet all are so closely related in essential principles that only general distinctions can be made. Up to the present time only the basket and drum types have been widely adopted; whether the table and wheel types will gain further prominence depends on several factors which experience alone will develop.

The Metallurgist in Steel.

While it is not conceivable that the mechanical engineer should ever come to occupy a subsidiary position in the manufacture of steel, it is distinctly a development of the times that the metallurgist is coming more into his own. One cannot lose sight of the fact that in the mad rush for increased tonnages in steel production which emphatically distinguished the decade of the nineties in the development of steel manufacture the physical and chemical characteristics of the steel produced were not sufficiently regarded. It was distinctly the day of the mechanical engineer. The problem was simply to increase the tonnage. With experience has come knowledge, both to the producer and to the user, and the burden to-day is upon the metallurgist.

Witness, for instance, the very prominent place which the problem of producing sound ingots occupied at the Leeds meeting of the British Iron and Steel Institute, as noticed in the report in this issue. This is purely a metallurgical problem, although in solving it upon a commercial basis engineering skill is necessarily brought into requisition. It is, however, not easy for one who reads the very able and interesting papers and discussions at the Leeds meeting to determine what is metallurgy and what is engineering in the matter presented. Perhaps it is too fine a distinction, or rather a distinction which should not be made at all in this form. There is coming into his own at present not so much the metallurgist as such, but the combination of the metallurgist with the mechanical engineer. The ideal is, of course, to have this combination realized in a single man—the metallurgical engineer. Though as long as "metallurgical engineers" in this sense are rare, we must rely on a hearty co-operation between the two individuals representing metallurgy and mechanical engineering respectively. And in this respect we are inclined to the viewpoint that in the older days the engineer did things, regulated occasionally by the limitations which the metallurgist had discovered, whereas to-day the metallurgist takes the initiative in accomplishing better results, and is merely aided by the engineer.

As an illustration that may not be without interest, a trifle over twenty years ago Mr. John A. Potter, then superintendent of the Homestead Steel Works, patented a process for producing sound ingots, covering a process which distinctly betokened the engineer and not the metallurgist. In essence, it was to compress the ingot hydraulically when in the mold, first upon its whole head, and then, by an ingenious means, to concentrate the same total pressure by means of a relatively small piston upon the central portion of the end, the walls of the ingot having meanwhile become so thick as to withstand an enormous pressure, much greater, of course, than could have been withstood by the walls of the mold alone. This was a mechanical engineering invention, designed to exert a very great pressure upon the steel, at a relatively small expense per ton. Not enough was known at that time about the behavior of steel to know precisely what was required to produce a sound ingot, and the idea was to "try on" an enormous pressure.

At the Leeds meeting at the beginning of this month Dr. J. E. Stead described a process developed by Mr. B. Talbot which he declared was "epoch making" and which aimed to produce a sound ingot—Dr. Stead asserted it was only necessary to square off the ends in order to have an ingot sound throughout—by the application of relatively little pressure, but exerted in such a way and at such a time, through the knowledge since gained of the behavior of steel in its freezing, as to produce the desired result. First purifying the steel by the use of aluminium or silicon, Mr. Talbot quickly strips the ingot, places it in the soaking pit for a short time, and then, when the central portion is still liquid, gives the ingot a few passes in the cogging mill, enough, for instance, to reduce a 20 x 25-in. ingot down to 18 x 18 in. In the horizontal position, the liquid steel flows partly into the pipe, and the reduction entirely eliminates the pipe. This one may call a metallurgical invention, mechanical engineering being merely the handmaiden of metallurgy.

The two papers on methods of producing sound ingots, presented at the Leeds meeting by Sir Robert Hadfield and Dr. Hans Goldschmidt respectively, also emphasize the same viewpoint. Before Sir Robert Hadfield set out to devise his methods of heating the ingot from the top with an intermediate protective layer of slag, he first devised a method of studying experimentally what is really going on in an ingot during solidification. This is the procedure of the metallurgist. As to Dr. Hans Goldschmidt's new method of using his anti-piping thermit, this is very different in principle from his older method using practically the same apparatus and is far more effective. It is now essentially a mechanical stirring process pure and simple, but a mechanical stirring process making use of a chemical reaction which would never have occurred to a mechanical engineer, but which, like the whole brilliant thermit process with its numerous applications in the iron and steel industries, could be invented and carried to commercial success only by a metallurgist.

Meeting of American Iron and Steel Institute.

The convention of the American Iron and Steel Institute was opened at Pittsburgh, Pa., on October 25th. A report of the convention is reserved for our next issue.

Meeting of American Institute of Mining Engineers.

The Cleveland meeting of the American Institute of Mining Engineers, which is to last to October 31, started with an informal social meeting on the evening of Monday, October 28. The professional sessions begin on October 29. A report of the convention is reserved for our next issue.

Meeting of American Institute of Chemical Engineers.

The fifth annual meeting of the American Institute of Chemical Engineers will be held in Detroit, Mich., from December 4 to 6, 1912.

1913 Meetings of American Electrochemical Society.

The Spring meeting, 1913, of the American Electrochemical Society will be held in Atlantic City, N. J., the Fall meeting, 1913, in Denver, Colo.

The exact dates have not yet been fixed.

The Western Metallurgical Field.

The Thiogen System of Fume Control.

The effective control of smelter fume has been a problem for years commanding the attention of metallurgical engineers. With the exception of sulphur dioxide the various constituents of the fume have been controlled, but this volatile vapor has continued to defeat all attempts to completely prevent its escape. The solids carried by the smoke have yielded to mechanical means, such as the baghouse and electrical contrivances, but it has been conclusively shown that mechanical devices are unable to handle sulphur dioxide gas, and as this element is one of the principal sources of damage to vegetation, the importance of its control is appreciated by all familiar with the subject.

In the Thiogen process it is proposed not only to control the noxious gas, but to make the detrimental factor become an asset. In smelting, each 1000 tons of pyrite ore discharges approximately 800 tons of sulphur and oxygen into the atmosphere, and by employing a reducing agent to combine with the oxygen it is planned to recover the sulphur and convert it into a valuable article of commerce. It has long been known that by uniting carbon with the sulphur fume and passing the product over limestone containing iron salts the gas is decomposed and sulphur precipitated. In the Thiogen system an oil spray is used to supply the carbon, and calcium sulphide forms the suitable accelerating agent. Calcium is preferential to potassium and other alkaline sulphides because of its lower cost and high infusibility. It has been found desirable to clean the gas as thoroughly as possible and to concentrate it before it is permitted to enter the combustion chamber.

The combustion department consists of a brick checkerwork chamber. A temperature of about 800 deg. C. is maintained by means of steam-injected burners, and as the oil-spray is driven into the chamber it rapidly vaporizes and mixes with the sulphur-laden gas. From this compartment the fumes pass into the reaction chamber. This has a length of 30 ft., with width and depth of 4½ ft. Like the combustion chamber it is filled with a checkerwork of brick, with the spaces of the checkerwork nearly filled with an equal mixture of sawdust and plaster-of-paris, moistened with water containing small quantities of iron salts. Small lumps of calcium sulphide are placed in the available spaces. The sawdust burns out and the $CaSO_4$ reduces to CaS more rapidly. The mixture is very porous and, as the gas is received, shrinks to about half the space in the checkerwork. The sulphur continues on to the condensing chamber, where it is cooled and precipitated as yellow sulphur In order to prevent the formation of arsenic, selenium or other minerals with the sulphur, should they be carried by the ore, a broad, low, slightly inclined condensing chamber is employed. Water sprays reduce the temperature of the gas and the undesirable compounds are deposited on projecting tiles provided in the chamber for the purpose. As the sulphur has a lower boiling point it continues on to the regular condensing chamber.

It has been found necessary to provide perfectly air-tight construction; otherwise the inward air pressure, caused by the heavy draft up the furnace stack, leads to air leakage, defeating the best efforts. The process is being tried at the Penn Chemical Smelter, Campo Seco, Cal., and results thus far have been encouraging. Naturally, problems have arisen that must be solved, and the engineers have not had sufficient time to make the most of the system, while the old smelter has not proven as satisfactory for the tests as desired. The hostility of the farmers to smelting has prevented the company from conducting comprehensive experiments at a more modern plant. The system is the invention of S. W. Young, professor of physical chemistry at Leland Stanford, Jr., University.

The costs attending operation of a plant of this nature are expected to be largely counterbalanced by the revenue derived from the sale of the sulphur. The present sulphur supply is obtained from sulphur wells of Louisiana and the natural deposits of Mexico, Sicily and Japan. The sulphur carried by pyritic ores is of excellent quality and an immediate market for the product is expected. In the past metallurgists have aimed largely at the control of the fumes, with scant attention paid to the value of the minerals carried off by the smoke. The great and pressing question has been the government of the fumes to an extent facilitating the operation of the smelter, and the most common practice has been the arrest of solids by the baghouse or similar devices and dilution of the gas with free air to meet the requirements of the law before transmission to the outer atmosphere. Consequently the Thiogen process marks a new and forward step. It aims not only at the extinction of noxious gasses, but also endeavors to raise the detrimental elements to the dignity of a by-product

Welfare of Employees.

It is noteworthy that the larger mining companies are paying more attention to the physical and social welfare of their employees, and that the relations between the company and the men are becoming more satisfactory. Without attempting to analyze the motives which inspire this movement on the part of the companies, the fact is being demonstrated clearly that it pays well in several ways. There are fewer accidents to pay for; prevention has been found cheaper than cure. The men are more contented; dissension is wiped out by a spirit of loyalty to the company. The best labor is retained because living conditions are made attractive and a premium put on permanent employment.

The Nevada-Douglas Copper Company of Nevada is one of the new companies to adopt the policies outlined and put them into practice. A large and well-equipped clubhouse has been erected for the employees. Thirty-five new cottages and houses of modern design have been provided for men with families.

The Homestake Company, at Lead, S. D., also has recently provided a club for employees, where they can spend their leisure hours amid good surroundings and apply themselves to the pursuit of either pleasure or profit.

The various companies in the iron mining districts of Minnesota and Michigan are paying a great deal of attention to the prevention of accidents in mills and mines, as well as providing for the comfort of their men. The generous use of guards, railings, screens and signs minimizes the possibility of preventable accidents. By adopting rules and regulations for certain

operations, and maintaining a safety-inspection committee to see that the rules are adhered to, the work is done with less risk. The scheme works well if not too complex for easy comprehension on the part of laborers who are not above the average in intelligence.

All in all, companies are learning that there is profit to all concerned if living conditions are made attractive in out-of-the-way places where comfort and refinement are all likely to receive too scant consideration.

Goldfield Consolidated.

The point of interest in the operation of the Goldfield Consolidated Mines Company, of Goldfield, Nev., is the persistence of good ore at a depth of 1300 ft. in the Grizzly Bear. This ore is showing an average value of $30 per ton and is being shipped to the smelter at Tooele, Utah. The results of the deep-level work are so encouraging that sinking is being continued to the 1400-ft. level.

On account of the delay in securing returns from the smelting ore, the monthly reports are being issued later than formerly.

During the month of August, 1912, the total production was 32,538 tons, containing $465,289, or an average of $14.30 per ton, of which 30,330 tons were milled with an average extraction of 89.31 per cent and 2208 tons were shipped of an average value of $15.26 per ton, the net recovery from all ore being $12.88 per ton. The total net realization to the company was $223,581, or $6.14 per ton.

Operating Costs.—The total cost of mining development, transportation, milling, office and general expense was $6.14 per ton, distributed as follows:

Mining, including stopping and development	$3.30
Transportation	.11
Milling	1.86
Marketing	.05
General expense	0.28
Bullion tax	0.03
Marketing ore shipped	0.53
Total cost of operation	$6.16
Miscellaneous earnings	0.02
Net cost per ton	$6.14

The Iron and Steel Market.

The iron and steel market has gained so much in strength that serious fears are now entertained for the continuance of the market movement beyond the period for which the mills are already filled up. The history of the market has been one of little else than ups and downs, and when an upward movement has run its course a reversal is regarded as almost inevitable, so that the desideratum, now that a fairly profitable price level has been established, is one of but slowly advancing prices. Advances in the past three months have not discouraged buying, but have rather encouraged the movement, and the large interests are now strongly committed to a policy of holding prices where they are, and of refraining from selling for very far forward delivery.

In several finished steel products, perhaps the majority, the volume of specifications lately booked is decidedly uncomfortable, as these specifications are upon contracts well below the present open prices, and they have been filed in such a volume as to make it certain that the mills will have to carry much of the tonnage over into the new year. During the late days of September and the fore part of October specifications reached the mills at a rate far exceeding the concurrent shipments, and while at the close of October the rate of specifying is somewhat diminished—probably due to the expiration of some important contracts October 1—the specifications are still in excess of shipments. Probably a fair estimate would be that outside of wire products and tubular goods the mills will carry over January 1st not far from three months of work, in actual specifications. Naturally enough, perhaps, the mills are prone to forget how eagerly they sought business a year ago at the lowest prices prevailing for a dozen years, and far lower than the record low prices, in relation to wages and the cost of materials, and in their changed attitude they are regretting that contracts at intermediate prices were written on such a scale that the business has banked up on them, when with less laxity a goodly portion of the tonnage might have been secured at the present more remunerative prices. Since the low point, almost a twelvemonth ago, finished steel prices have advanced an average of between $6 and $6.50 per net ton, but the average invoice price of shipments being made to-day by the large mills is probably no more than $3 a ton above the low point. With the smaller mills, which as a rule do not make contracts, the average realized price is naturally much higher, and beyond this is the fact that the smaller mills are now able to realize upon a large part of their shipments, not merely the present openly quoted prices which are regarded as "the market," but much higher prices, due to the charging of premiums. Such premiums in the case of merchant steel bars and plates, are ranging from $2 to $4 a ton above the regular market prices of 1.40 cents on bars and 1.50 cents on plates.

While much of the buying has been encouraged by the fact that prices were advancing and deliveries were growing harder and harder to secure, it is developed practically beyond question that the consumptive demands of the country have at least grown up to the capacity, if they do not now actually exceed it. It will be recalled that immediately after the financial panic of October, 1907, when the iron and steel trade found itself with output reduced to one-half the former record rate, and with a large amount of new construction in progress, the common statement was that it would require a period of years for demand again to grow up to capacity. It seems to have been somewhat difficult for the trade to realize, in recent months, that the five years intervening since that famous panic have actually elapsed, and to realize also that while at that time there was a large amount of new construction in progress, and carried to completion during the ensuing two or three years, the additions to capacity of late have been relatively small. The actual production of pig iron has increased very little in five years, for the fact is that in October, 1907, pig iron was being made at the rate of 28,000,000 tons a year, whereas to-day it is being made at the rate of 31,000,000 tons. The present capacity is undoubtedly greater than the production, but we have had an average advance of $3.50 in pig iron, from the low point at the beginning of this year, and an average advance of $6 a net ton in pig iron from the low point of last November, and with such encouragement to producers the actual fact is that pig iron is being made at the rate of only 31,000,000 tons a year. The history of the industry has shown a doubling of pig iron production every ten years, on an average, which means two successive increases of 41.6 per cent in five year periods, whereas in the past five years we find an actual increase of less than 10 per cent. Even on the assumption that the production in 1907 represented a rate considerably above normal the present production is not large in the light of past performance, and the pressure upon producers is readily explained.

Pig Iron.

There has been active buying of pig iron in all markets, with almost continuous advances in prices at one point or another. The average advance in the entire market has easily been 75 cents a ton for the month. The blowing in of idle merchant furnaces has been retarded by the great scarcity of coke, which has advanced from $3.75 to $4 at Connellsville ovens for prompt and spot shipment, with contracts for the first half of the new year at about $3. We quote: Bessemer, $17; basic, $16, and No. 2 foundry, $16.50, all f. o. b. valley furnaces, or 90 cents higher delivered Pittsburgh; No. 2X, delivered Phila-

delphia, $18 to $18.50; No. 2 foundry, f. o. b. Chicago furnaces, $17 to $17.50; No. 2 foundry, Birmingham, $14.

Steel.

There is practically no market in billets and sheet bars. The mills are oversold for this year, and are carrying over so much tonnage, besides being under pressure from their own finishing mills, that they are not offering any steel on contract for next year. Occasional small lots are picked up from mills and jobbers, and the market as far as it can be quoted represents an advance of fully $2 a ton in 30 days. On the basis of actual sales, but with no certainty that additional purchases could be made at these figures, we quote: Bessemer billets, $26 to $26.50; Bessemer sheet bars, $26.50 to $7; open-hearth billets, $27 to $27.50; open-hearth sheet bars, $27.50 to $28; rods, $29 to $30, f. o. b. maker's mill, Pittsburgh or Youngstown.

Finished Steel.

During October, wire products advanced $1 a ton, black and galvanized sheets $2 a ton and blue annealed sheets $1 a ton. Plates, shapes and bars advanced $2 a ton. Prices given below represent minimum quotations on contracts, with prompt deliveries in the majority of cases commanding substantial premiums. Prices are f. o. b. Pittsburgh unless otherwise stated.

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill, except Colorado.

Plates, tank quality, 1.50 cents.

Shapes, 1.50 cents.

Steel bars, 1.40 cents.

Common iron bars, 1.60 to 1.65 cents, Pittsburgh; 1.60 to 1.70 cents, Philadelphia, 1.50 to 1.55 cents, Chicago.

Steel hoops, 1.50 cents.

Sheets, blue annealed, 10 gage, 1.60 to 1.65 cents; black, 28 gage, 2.25 to 2.35 cents; galvanized, 28 gage, 3.40 to 3.50 cents; painted corrugated, 2.35 to 2.45 cents; galvanized corrugated, 3.45 to 3.50 cents.

Tin plates, $3.60 for 100-lb. cokes.

Merchant steel pipe, ¾ to 3-in., card weight, 79 per cent off list.

Steel boiler tubes, 3½ to 4½-in., 72 per cent off list.

Standard railroad spikes, 1.80 cents.

The Non-Ferrous Metal Market.

High prices continue to prevail for the principal non-ferrous metals, and the markets generally are in good condition. Foreign activities are exercising a marked influence on domestic markets. Some spelter has been imported and speculation in tin has been reflected in fluctuating prices.

Copper.—The unsettled conditions abroad have been the cause of a dull market in this metal. The last New York quotations are: Lake, 17⅝@17⅞ cents and electrolytic 17.30@17.40 cents.

Tin.—Statistics published on Oct. 1 tended to lower the price of this metal. The fluctuations in price were caused almost wholly by speculation. A slight premium for spot tin in the domestic market prevailed for a short time, but disappeared later. The latest quotation is 50 cents, New York, for October delivery.

Lead.—Prices remain unchanged at 5.10 cents, New York, and 4.90@4.95 cents, St. Louis.

Spelter.—This market has shown a dullness due to the fact that buyers are quite well supplied. Some metal has been imported. Prices remain high, however, the last quotations being 7.30@7.35 cents, St. Louis, and 7.45@7.50 cents, New York.

Other Metals.—There is a good demand for aluminium at 25@26 cents, New York. Higher prices prevail for antimony on account of the shortage in ore supplies. The last quotations range from 9 to 10¼ cents for various grades. The quicksilver market is steady at $42 per flask of 75 lb., New York, and $41.50 at San Francisco.

Sterilization of Water by Ozone in St. Petersburg.

The Uprava (Magistrate) and the Duma (City Council) of the City of St. Petersburg in Russia, have agreed unanimously to adopt the ozone method in connection with rapid filtration for the cleaning and sterilization of the water for the city, supplied by the water works at Spalernaja, in view of the good results obtained from ozone water works already in operation at Penkowaja.

Advertisements for proposals for the plant have already been issued, the city having appropriated 10,000,000 rubles for the project. The awarding of contract, based on estimates received, is to take place in the near future.

The original ozone purification plant of the water works of St. Petersburg was described in detail in an article by Dr. G. Erlwein, in our Vol. IX, p. 213 (April, 1911).

CORRESPONDENCE.

Exothermic Steel.

To the Editor of Metallurgical and Chemical Engineering:

SIR: I see in your issue of September 1 an article describing "Exothermic Steel," a new trade product invented by Mr. George Fogler and described by W. O. Amsler, D.Sc.

The fact that the method is patented and that the description is sponsored by a scientific man challenges serious attention to the statements made and forbids us dismissing them as merely fanciful.

The statement is baldly made that a mixture of feldspar, bauxite and lime acts as a reducing agent on iron oxide, reducing it to metallic iron, with a strong exothermic reaction. The aluminium compound in these fluxes is said to act reducingly upon the ore. In practise this reaction is said to be so strongly exothermic as to require some carbon to be admixed in order "to keep the temperature within safe limits."

I am sorry to see any scientific man make such statements. The statements are mere bosh. The chemical equations given as representing the reactions are erroneous, inasmuch as potash feldspar is $KAlSi_3O_8$, and not $KAl_2Si_3O_8$; and while the extra free atom of aluminium is needed to complete the equations given and to supply the exothermic heat talked about, yet unkind Nature has not supplied it in potash feldspar.

The author further talks about running a "matte" furnace with such a charge, with some carbon admixed to keep the temperature down *(sic)*, and blowing in oil or gas flames by air under pressure. The metal does not appear in this "matte" in its free state, but "exists in a state of solution or similar condition, or perhaps even as a silicate of iron, although the writer is inclined to doubt this."

I share his doubts; in fact, I will go him several better, and *doubt the whole thing* until some reputable metallurgist describes the operations in terms which are understandable, and makes statements which are believable. JOS. W. RICHARDS

Lehigh University.

* * *

To the Editor of Metallurgical and Chemical Engineering:

SIR: In the September issue of your journal an article written by Mr. Walter O. Amsler, D. Sc., Pittsburgh, Pa., under the title "Exothermic Steel," in which he sets forth the theory or explanation of an "exothermic reducing reaction between a metallic oxide and a compound silicate of aluminium by which the formation of aluminium oxide takes place." By the use of felspar and bauxite together with limestone to make a fluid slag, he states, the temperature would run too high and therefore enough carbon is charged to reduce a part of the (metallic) oxide by formation of carbon oxides to keep the temperature within safe limits.

The author of this article then proceeds to give us the chemical formula of felspar as ($KAl_2Si_3O_8$). This appears to be an error, but the same formula is used in the two equations which

are intended to represent the reaction supposed to take place.

The chemical formula of felspar as given by authorities on the subject is ($KAlSi_3O_8$) or ($K_2OAl_2O_3\,6\,SiO_2$) and by the use of this formula no equations can be written showing the reaction without carbon as given by the author.

In the second equation where the presence of carbon is considered we can only show reduction directly due to the carbon alone.

Exception must be taken to the writing of hydroxide in an equation representing high temperature reaction where it would be impossible for hydroxides to remain as such.

I do not attempt to suggest that steel possessing special qualities could not be made by the process; but I make these remarks in the hope that the author will withdraw this chemical explanation or make it compatible with our present knowledge of chemistry of silicates.

Pittsburgh, Pa. F. GELSTHARP.

* * *

To the Editor of Metallurgical and Chemical Engineering:

SIR: It is particularly gratifying that Dr. J. W. Richards, of Lehigh University should take such vigorous exception to certain statements in the article on "Exothermic Steel" that appeared in your September issue, and that he should italicize his doubts "of the whole thing." The matter must be original to say the least.

It is natural that the pedantic scientific mind should be conservative, if anything, and that it should require anything out of the accepted scheme of things to come from a "reputable metallurgist who makes statements that are believable."

If it is a bald statement to say that feldspar and bauxite with lime react upon an iron oxide in the manner stated in article to reduce the iron with the evolution of heat, it is also a statement of a bald fact. I realize that the exothermic reaction is contrary to the accepted theory of the construction of feldspar and bauxite, but it is really not my fault that these things happen.

The formula for feldspar as given in the article is not as accepted by the authorities, but I can challenge my critic to prove, in a practical way, that somewhere in the reduction by this process, such a reaction as given does not take place. Unless carbon and silicon have different properties when in this flux than generally attributed to them, it would appear to me that the oxidation of aluminium must be assumed to account for the evolution of heat that undoubtedly appears.

The paragraph of the article referring to the rise of temperature being too great unless carbon is used, is capable of misinterpretation. The heat could no doubt be taken care of by using a proper lining, but the temperature would be higher than necessary. Neither is it made clear that the use of too much flux in proportion to the charge of ore will not give good results as it tends to choke the furnace. Yet when using a certain proportion, the resultant metal is so hot that it can be used for welding purposes.

It surely would require a bold theorist to describe the "matte" (this word is used for want of a better one) furnace, its operation and cost sheet together with that of the open-hearth precipitating furnace if such a plant had not been in actual operation.

In conclusion this insurmountable fact obtrudes itself: the process is used to produce a steel that is being sold. If it were all bosh as Dr. Richards is pleased to call it, the steel would not be purchased by our government for use where it gives better service than any other steel. If any critic will submit a better chemical explanation of the matter than the one given it will be thankfully acknowledged. But in the meantime it must be remembered that the process is in actual commercial use, and the exact nature of the chemical reactions taking place must be considered as an academic problem. Constructive criticism will be welcomed.

Pittsburgh, Pa. WALTER O. AMSLER.

Typical Analyses of Iron Blast Furnace Gases.

To the Editor of Metallurgical and Chemical Engineering:

SIR: The accompanying table may be of interest to those engaged in the blast furnace end of pig iron manufacturing. It is compiled from 860 different tests and covers a range of twenty odd furnace linings. It is as near relative as can be put together with ordinary methods of analyses.

A close examination will disclose a few variations from a direct comparison. This is particularly so in the percentage of hydrogen, which varies at different times of the year and depending upon the amount of water used in wetting down the materials before changing and in the varieties of cokes used.

TABLE SHOWING QUALITY OF GASES PRODUCED IN THE BLAST FURNACE, USING NATURAL AIR AND WITH THE CORRESPONDING COKE CONSUMPTIONS.

Pounds of coke per ton of metal.	Product.	Gas Analyses. CO_2.	CO.	H.	N.
3200 to 3400	Spiegel	6.2	30.9	2.3	60.6
3400 to 3500	Spiegel	7.0	30.0	3.5	59.5
4800	Ferro-silicon	3.5	32.5	2.0	62.0
5300 to 5400	Ferro-manganese	4.6	32.6	1.2	61.6
5400 to 5500	Ferro-manganese	3.6	32.2	2.2	62.0
5500 to 5600	Ferro-managese	5.0	28.0	2.6	64.4
5700	Ferro-manganese	3.4	33.8	2.4	60.4
5800	Ferro-manganese	4.3	33.1	1.7	60.7
5900	Ferro-manganese	3.8	32.9	2.4	60.7
6000	Ferro-manganese	5.0	34.4	2.7	57.9

Braddock, Pa. J. G. W.

The Electric Steel Furnace and the Use of Titanium in Foundry Practice

To the Editor of the Metallurgical and Chemical Engineering:

SIR: In the article by Mr. Paul Girod entitled "The Electric Steel Furnace in Foundry Practice" in your October issue, page 663, this passage occurs: "Recently a very important improvement has been realized by introducing into electric steel practice for castings the use of special titanium alloys such as manufactured by the Société Anonyme Procédés Paul Girod of Ugine, Savoie, France."

Allow me to point out that if this practice is considered abroad as a very recent improvement it is not so in the United States, as such alloys for a number of years have been manufactured under the Rossi patents, some of which were granted ten years ago. Many thousands of tons of steel during the past four years have been treated with this American product. Regarding the use of titanium alloys in connection with steel made in electric furnace; early in 1908 the writer was using such alloys in steel made in electric furnaces of from 2 to 5 tons capacity, recognizing the fact that by such treatment only was it possible to obtain a product uniform and thoroughly deoxidized.

I am glad that Mr. Paul Girod realizes that titanium will improve electric steel. Three years ago in Italy Major Stassano made a similar statement recommending the use of titanium alloys in making electric steel castings. Mr. Girod further remarks, "Even very small additions of these (titanium) alloys render the steel perfectly quiet and insure the castings to become very dense and free from any blowholes. The number of lost heats can be very much diminished." This means that

titanium additions will thoroughly deoxidize the steel, giving a uniform product.

Mr. Girod frankly admits that titanium reduces the number of lost heats; why is this, considering that the function of the electric furnace is to deoxidize the steel? Because deoxidation is only accomplished if carbide of calcium slag be formed. Every one experienced in the use of the electric furnace knows how difficult it sometimes is to form this carbide of calcium slag; and, personally, basing my statement on experience with several hundreds of heats made in electric furnaces, I will say that in most heats this result is not always perfectly obtained. Consequently if the steel is not deoxidized then why use an electric furnace for making steel castings if it still be necessary to finish the deoxidization by using so powerful a reductor as titanium? Is it to get the sulphur and phosphorus as low as 0.015 when specifications called only for under 0.030 or 0.040? Every steel maker knows that when tensile strength, manganese, and carbon are specified, they have only phosphorus at their disposal to raise the tensile strength, the value of phosphorus as a strengthening agent being about 900 lb. per square inch for each 0.01. Such steel can be made more simply and far cheaper in open-hearth furnaces using as deoxdizer an addition of titanium alloy in the ladle.

I will add to Mr. Girod's statement as follows: A great feature of titanium addition is that the titanium by oxidation is transformed into titanic acid which fluxes all the slag held in suspension in the steel after it has been tapped into the ladle and the quantity of slag so held in the steel is very large when the calcium carbide slag has been formed, the latter being very pasty. Allow me to point out, also, that while ferro-alloys of titanium and silicon combined may be a new way of placing titanium on the market, their use will prove a much more complicated operation than separate additions of ferro-titanium and ferro-silicon. Ferro-titanium alone is very useful, but when an equal quantity of silicon is combined with the alloy the silicon is oxidized last if the deoxidation of the bath has not been completed by the titanium, but if it has the silicon will be dissolved in the steel, thus raising the silicon content to a point very often over the limit imposed by the specifications.

In the case of steel made in the electric furnace, it will very often be found that the silicon is too high, a condition brought about by additions of ferro-silicon during the deoxidation period, or more often by the melting of the roof of the furnace, which introduces silica into the slag, this silica being in turn reduced by the calcium carbide present.

Niagara Falls, N. Y. N. Petinot.

Two Aspects of "Conservation" and the Niagara Power Situation.

To the Editor of Metallurgical and Chemical Engineering:

Sir: I am rejoiced to see the strong stand which Metallurgical and Chemical Engineering in the issue of September 12th has taken editorially against the restriction of power development of Niagara Falls. From an industrial viewpoint every cubic foot of water that goes thundering over the great cataract unutilized is sheer continuing waste of national resources.

"Conservation" which conserves only gigantic waste strikes the ordinary citizen as being very far from an ideal display of governmental activity. The distribution of power from Niagara, now extending over a radius of many miles, has been of general benefit and the cessation of this development is a thing to be lamented not only as a purely industrial matter, but out of regard for the welfare of the whole people.

I am by no means deaf to the æsthetic and sentimental arguments for the restriction of power development at Niagara, indeed I would willingly agree that the country might be better off for "letting in the jungle" upon certain spots now obnoxiously populous. But granting the general weight of the sentimental argument, I have not been able to see how it applies to Niagara, which was already robbed by its sordid environment of most of its æsthetic value long before electrical developments there began.

Could the scene be preserved in its pristine magnificence, surrounded by virgin forest, and silent save for the deep-voiced roar of the rainbow-crowned cataract, it might have been worth the while. For a good many years, however, the surroundings have gradually grown more and more tawdry and sordid. The forests have long since been swept away. The landscape has been defiled with shabby hotels and cheap factories and the voice of the waters has been drowned by screeching steam whistles, the clatter of the street, and the raucous voices of hackmen and guides. The fact is, that Niagara as a majestic spectacle has never belonged to the present generation. It was given up to noisy and offensive exploitation long before the first dynamo was set spinning at its brink.

"Saving Niagara," from the æsthetic standpoint, is a sorry joke, like saving forests by selling the charred slashings to the Government after every stick worth cutting has been carried away. But the cataract, no longer able to teach its primal majestic lesson, can at least teach humanity something of the beauty of labor. If I read its mission aright it is to scatter productive industry over the face of the country for a radius of 500 miles or more, to bring the means of efficient industrial development within the reach of hundreds of communities. Such a distribution of power will not only build up material things, but it will help serve the things of the spirit by opening wide the gates of industry instead of closing them prisonwise on a few overgrown and unlovely manufacturing cities.

As a citizen, hopeful of my country's future, I do not like the Great Industrial Center. From even the material standpoint it is too often merely a center of squalor, poverty, and wretchedness, where all the evil forces that arise from these are felt with their fullest power. We, in Massachusetts, have had ample opportunity to observe the effect of great aggregations of underpaid, underfed, low-grade labor seething with unrest and only temporarily quieted by the clubs of the police and the bayonets of the militia. Our great industrial centers have become powder magazines, of their own loading, upon which too many of the self-styled "better class" sit and complacently smoke. And I have long believed that the best remedy for these conditions is to be found in further reaching opportunities for industry, in the equalization of working facilities over broad stretches of country, and that the widespread distribution of transmitted electrical power is one of the most efficient means for promoting this end. It has been successful in saving scattered industries abroad. It is showing signs of success in building up such industries here.

When the power of Niagara is diffused over the states of New York and Pennsylvania and the Province of Ontario, communities now moribund will spring into active life again, and we shall see the prosperous and active manufacturing town of a generation ago here, there, and everywhere, supplanting the great industrial center that is coming to be from the viewpoint of the sociologist a sort of outwork of Tophet. If the governments of the United States and of the Dominion of Canada could get together and encourage the development of Niagara, and the boards of trade in all the towns within its radius of distribution could get busy and take advantage of the opportunity, the cataract would be doing work of which both nations could be justly proud, instead of failing as a spectacle and shirking its most obvious utility.

If there are those who from motives of curiosity would wish to see what Niagara was like when it was going to waste, it would not be difficult to arrange on, say, the Fourth of July and Dominion Day, joint local holidays, of which we have none too many, on which the great stream could be turned in the main into its former channels for the sake of "Auld Lang Syne."

At present it is neither adequately ornamental nor properly useful.

Boston, Mass. Louis Bell.

The Death of Dr. Morris Loeb.

Dr. Morris Loeb, president of the Chemists' Club, of New York, and former professor of chemistry in New York University, died at Seabright, N. J., Oct. 8, 1912, from typhoid fever and double pneumonia after a brief illness, not yet fifty years old.

At a meeting of the trustees of the Chemists' Club, held on the evening of Oct. 8, the following preamble and resolution was ordered to be filed:

"Whereas, Morris Loeb, the president of the club, has been taken from us by death, and

"Whereas he was the leading spirit in bringing to fulfillment ambitions and plans that had long been ours, and

"Whereas he was always ready to shoulder burdens and to give help, and

"Whereas he was a man of order, and of integrity in mind and heart, sincere in scholarship, living without malice or scorn, speaking no evil, and generous in judgment, and

"Whereas we were drawn to him by ties of deep and abiding affection, now, therefore, be it

"Resolved, that we make this minute of our poignant grief at his passing, and that we cherish his memory as another of his great gifts to science and to humanity."

* * *

THE LATE MORRIS LOEB.

Morris Loeb was born in Cincinnati on May 23, 1863, a son of Solomon and Betty Galenberg Loeb. His father was one of the founders of the banking firm of Kuhn, Loeb & Company. He was educated at the Dr. Julius Sachs School and later in Harvard University, where he received the degree of Bachelor of Arts in 1883. In 1887 he graduated from the University of Berlin with the degree of Doctor of Philosophy and for a year thereafter he studied at the Universities of Heidelberg and Leipzig.

From 1888 to 1889 he was assistant to Prof. Wolcott Gibbs at Harvard University and from 1889 to 1891 docent of chemistry at Clark University. Thereafter, for sixteen years, from 1891 to 1906, he was professor of chemistry and director of the chemical department of New York University. This position he resigned in 1906 in order to take up private chemical research of his own and to devote himself more largely to philanthropic and commercial work.

In 1895 Professor Loeb married Miss Eda Kuhn, of Cincinnati, of the Kuhn family which represented the second branch of the founders of the banking firm of Kuhn, Loeb & Company. Mrs. Loeb survives him.

Distinguished as Professor Loeb was for his original work in chemical research, of even greater influence was his indefatigable work for the Chemists' Club in New York and thus indirectly for American chemistry. "He was a charter member at the organization of the Chemists' Club in 1898. Twice he was vice-president and twice president. It was during his first presidency in 1909 that the idea of having a clubhouse of our own, an idea which had been vaguely in our minds before, now took definite shape. His wise counsel, his time and his generosity were unselfishly placed at the disposal of the Chemists' Club, and it is not too much to say that to him more than to any other one man the chemists of America are indebted for a chemists' club and clubhouse absolutely unique in the world. When we occupied the new club quarters, this same wise counsel and generosity were invaluable. The entire furnishings of Rumford Hall, of the Priestley Room, of the library and museum were at his expense. Scarcely a room in the club is without some mark of his thoughtfulness and generosity. Though his path through life was smoothed more than happens to most of us, his days were filled with activity, and he was a living embodiment of how fivefold it increases the value of a benefaction when the giver's time and counsel and interest go with it. His many memorials in the clubhouse will not be needed to make us remember him."

In 1911 Professor Loeb and his brother contributed $50,000 for the Wolcott Gibbs Library at Harvard University, where he had previously founded the Association of Harvard Chemists.

Professor Loeb was a generous patron of music and art, a philanthropist and public citizen. At the time of his death he was a member of the Board of Education of New York City. His charities were many and by no means limited to his own race. He was president of the United Jewish Charities Building, a member of the American Jewish Committee, a trustee of the Jewish Theological Seminary of America, and formerly president of the Jewish Agricultural and Industrial Aid Society. He was founder of the Betty Loeb Musical Foundation and a director of the Educational Alliance.

The following is a list of the papers which Professor Loeb published in the twenty-seven years during which he worked as an original investigator in chemistry:

Action of Carbonyl Chloride on Ethenyldiphenyldiamine (Diphenylacediamine), *Ber., 18*, 1885, p. 2427-8.

A New French Chlorate and Perchlorate Plant.

Near the little village of Epierrẽ, between Chambéry and Modam in the French mountains, a new electrolytic chlorate factory has been erected in 1911. This new plant is situated in the industrial valley at Maurieune, where the power from the Arc River is already being utilized for numerous large electrochemical plants. Industrially it is one of the most interesting valleys of Savoy. The proprietors of the plant are Messrs. Davey-Bickford-Smith & Co. of Rouen, who are well known all over the world for their explosives. The factory is called the Usine de la Corbière in St. Pierre de Belleville (1 kilometer from Epierre).

The electrical power is produced from the water of a little river coming down at St. Pierre de Belleville from a height of 1100 meters over sea, while the power house is at the level of 369 meters so that a fall of 731 meters is utilized. The power produced is in the average 1500 h.p. (varying from 800 to 3000 h.p.). The water used by one turbine (500 h.p.) at full load is 70 liters per second.

The upper part of the pipe line is a pipe of 2500 meters

POWER HOUSE AND CHLORATE PLANT.

length of reinforced concrete. The first upper part of the steel tube line has an inclination of about 55 degrees, the lower part, a welded steel tube, 75 to 80 degrees inclination. The total length of this iron-steel tube is about 1500 meters. The difficulty of fitting up this last part of the tube was very great. It was done by the well-known firm of Joya et Cie in Grenoble, who are specialists in this matter.

The power house has room for six high-pressure turbines or Pelton wheels. Five have been installed and are coupled to the driving shaft of the dynamo, which generates 1500 amperes at 220 volts, the speed being 450 r.p.m. The turbines and dynamo are provided with good regulators and all apparatus generally used in order to avoid any kind of accidents. The continuous current produced is carried to the electrolytic plant.

The turbines were furnished by J. J. Rieter in Winterthur, Switzerland, and the dynamo by Schneider & Co., Champagne sur Seine, near Paris.

Electrolytic Plant.

Three hundred cells producing about 5 tons per day of chlorate of potash are installed. The electrolytic cells and the process were invented by M. Couleru, of Paris, expert in chlorate and perchlorate manufacture. The anodes used are very thin sheets of platinum, the cathodes and the cells are of cast iron. For insulation mica is used. The apparatus is working continuously and so is the feeding of fresh liquors.

USINE DE LA CORBIÈRE.

The solution leaving the cells is conducted to the cooling tanks.

Instead of platinum graphite is also used and this use is very interesting at the present time since platinum is very dear.

Large concrete or iron tanks are used for the cooling of the solutions. Artificial cooling in the electrolytic cells or in these tanks may be employed successfully in order to save time and to reduce the cost of the first installation. The warm water obtained by cooling can be used for several purposes.

The raw chlorate is dissolved in hot water for refining. The apparatus used is the same as generally employed, namely, iron tanks, brick pans, drying installations, grinding mills, etc.

During the dry summer of 1911 the water was very scarce and in order to increase the power two other waterfalls were purchased at Epierre and the total power is now in the average of 3500 h.p. The excess power will be used for other products.

The chlorate plant at Epierre has been recently purchased by the International Chlorate Syndicate. The work at Epierre is continued by the Société Universelle d'Explosifs of Paris, and the manufacture of perchlorates, especially of ammonium perchlorate, will be taken up. Chlorate of sodium will also be produced on a large scale. Both products will be used for explosives only.

Iron Ore Concentration in Minnesota.

Editorial Correspondence.

The production of merchantable iron ore, by means of wet concentration, from material which is too low-grade for profitable reduction in the blast furnace, is one phase of the great iron and steel industry which is in its infancy. That it has been successfully done on a large scale, leads to the belief that it is an important step toward the genuine conservation of our iron resources, and one that will be followed by others which, in time, will make available much ore now without commercial value. This means not only the utilization of low-grade deposits, but the conservation of the best ore for special purposes, or for raising the average grade and quality of a large tonnage of less desirable ore.

Special systems of concentration have had to be devised to meet the requirements of iron-ore production. The intrinsic value of a ton of iron ore is not great enough to warrant too elaborate a system of treatment, while smelting conditions demand an ore with as much lump and as little fine as possible. Tonnage and physical condition of the product, therefore, become important factors in this business. The former is equally important in the treatment of other low-grade ores, such as gold or copper. In these cases, however, it becomes necessary to resort to elaborate systems of grinding and fine concentration, which, fortunately, can be dispensed with in the concentration of iron ore.

In point of tonnage capacity of a single plant, there are no other ore-dressing mills in the United States which approach the magnitude of the largest iron concentrator. The great copper concentrating mills of Utah and Arizona, having individual capacities ranging from 3000 to 12,000 tons in 24 hours, are still small compared with the Trout Lake mill of the Oliver Iron Mining Company, with its capacity of 35,000 tons in 20 hours. And yet, owing to the more complex flow-sheet of the former, and consequently the larger number of machines used and greater acreage covered, they make an impression more nearly in keeping with their magnitude than does the iron concentrator.

Trout Lake Mill, Oliver Iron Mining Company

The first and larger of the two iron concentrating mills in Minnesota, was built by the Oliver Iron Mining Company, on Trout Lake, near the western end of the Missabe range, where the ore is lower-grade than it is farther East. Here, also, the company has built the model town of Coleraine, beautifully situated on the north shore of the lake, and made attractive by substantial buildings, good schools, broad streets, cement curbing and sidewalks, and a system of artistic street lighting.

An exterior view of the mill is given in Fig. 1 and a flow sheet in plan and elevation in Fig. 2. The railway approach to the mill is over a long fill of earth and rock removed in stripping the iron deposits. This approach ends in a steel trestle, shown in the figure, reaching a height of 110 ft. above the ground, and giving the necessary elevation for a gravity flow of ore through the mill.

Unit Construction.

The flow-sheet, Fig. 2, represents one of the five units, each under independent control. The capacity of each unit is 350 tons per hour, and as the mill is operated during two shifts of 10 hours each, or 20 hours per day, the capacity of the whole mill is 35,000 tons per day. The crude-ore bin for each unit will hold 500 tons of ore, or about 1½ hour-supply for the unit. The views shown in Figs. 4 and 5, although taken in another plant, represent similar construction in a unit of the Trout Lake mill.

As shown in the flow-sheet, the concentrating machines of a unit are one conical screen (2-in. openings), two 25-ft. log-washers, two 18-ft. turbo-washers, and twenty Overstrom con-

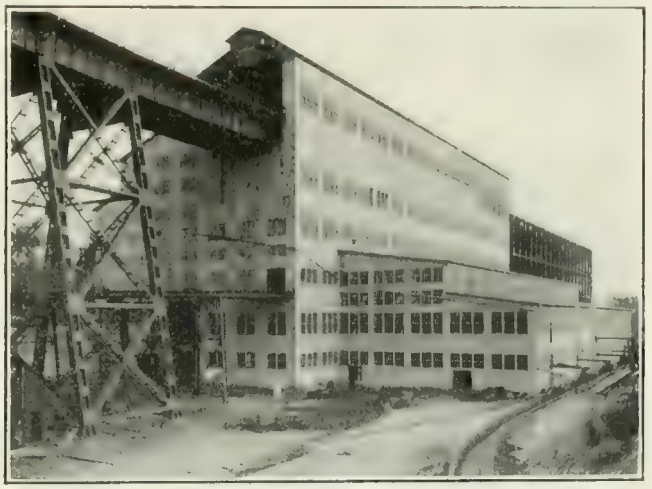

FIG. 1.—IRON-ORE CONCENTRATOR, OLIVER IRON MINING COMPANY.

centrating tables, with the necessary complement of settling tanks, pumps and bins. The ore is sluiced from the bin onto a grizzly (6-in. openings), where large pieces of waste rock are

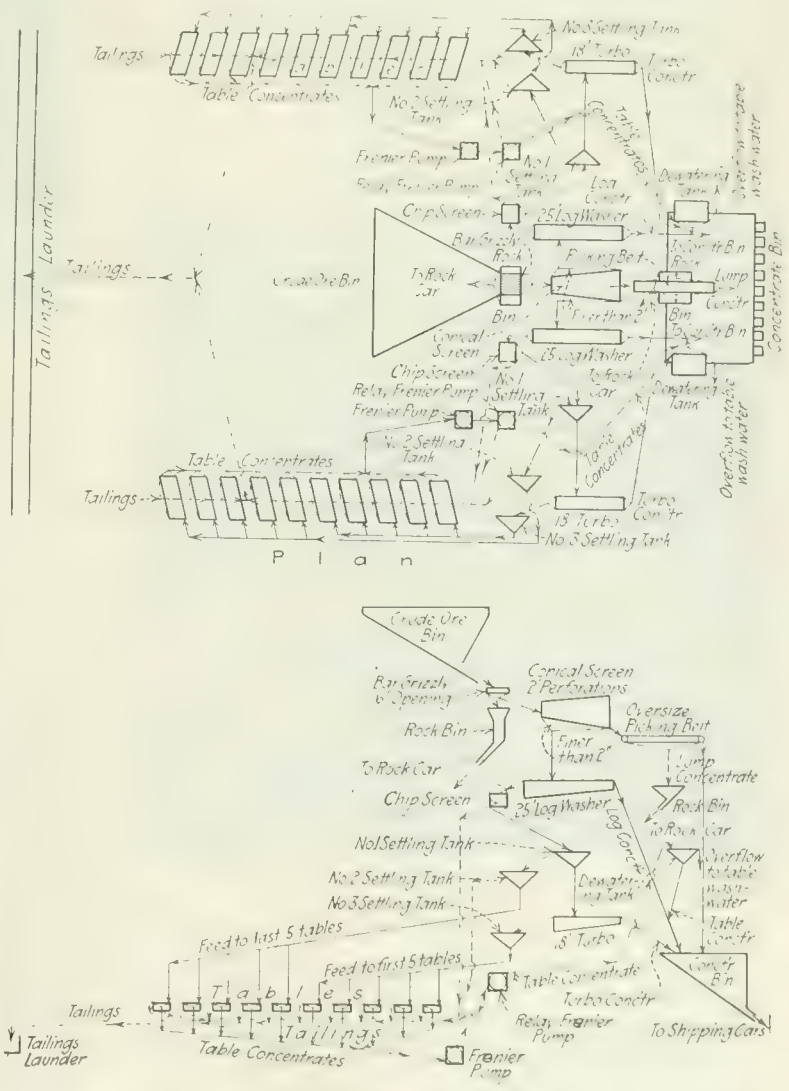

FIG. 2.—FLOW SHEET, TROUT LAKE CONCENTRATING MILL, OLIVER IRON MINING COMPANY, COLERAINE, MINN.

sorted out, and large pieces of ore broken to pass on to the conical screen. The oversize of the latter passes onto a picking-belt (Fig. 5), the rock being picked out and discarded, while the lump concentrate passes on to the bin.

The 2-in. undersize of the screen flows to the log-washers on either side (Fig. 4). These machines produce a coarse concentrate which passes to the bin, the overflow being thickened and

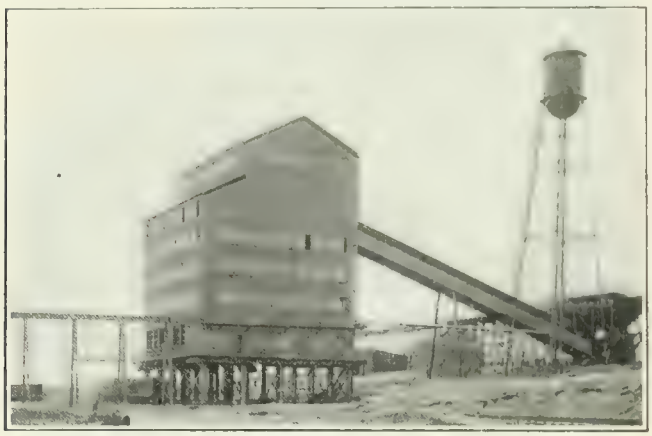

FIG. 3.—IRON ORE CONCENTRATOR OF WISCONSIN STEEL COMPANY, NASHWAUK, WIS.

treated in the turbo-washers, which are practically smaller log-washers in which the feed is kept well agitated by numerous jets of water rising from the bottom of the casing. Between the logs and turbos are so-called "chip" screens or trommels, to separate and remove "chips" of rock which are carried in the overflow of the log-washers. The turbo-washers produce a smaller size concentrate, and their overflow is thickened, and

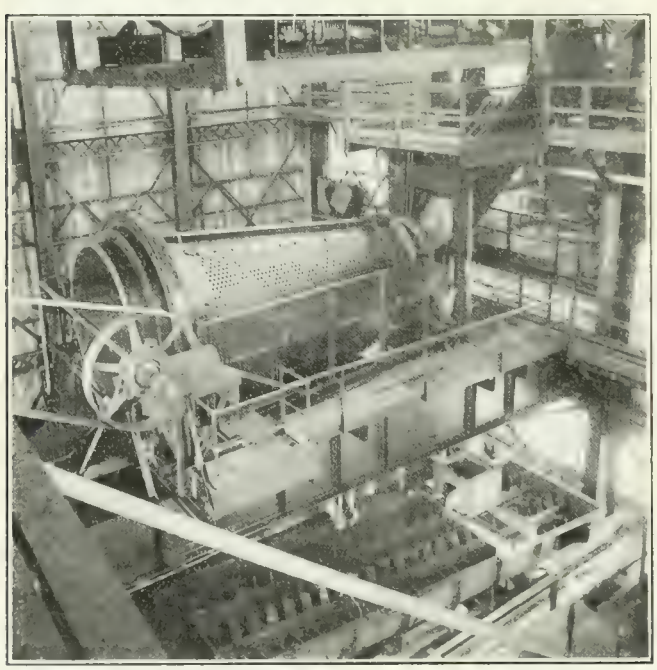

FIG. 4.—INTERIOR OF CONCENTRATOR OF WISCONSIN STEEL COMPANY, NASHWAUK, MINN., SHOWING SCREEN AND LOG WASHER.

treated on tables. The table feed is clearly shown in the flow-sheet. The table concentrate is elevated by Frenier pumps, in two stages, dewatered and sent to the bin.

A 100-hp motor drives the conical screen, log and turbo-washers, and a 15-hp motor serves the twenty concentrating tables. The perforated plates of the conical screen are ½ in. high-carbon steel, and last about 100 days. The chilled-iron paddles on the logs last from five to six months. The decks of the Overstrom tables have been remodeled to suit the conditions, by removing the riffles and substituting a corrugated wood surface. This change resulted in increasing the efficiency of this department nearly 50 per cent.

The grade of the crude ore as it comes from the pits ranges from 35 to 42 per cent iron. The concentrate averages 57 per cent iron, and represents about 67 per cent by weight of the crude ore treated. The phosphorus content of the concentrate is slightly greater than that of the crude ore. All tailings are combined and sent to the Lake through a concrete flume, seen at the right in Fig. 1.

The pump and power station is situated on the shore of the lake, about 1¼ miles below the mill. The power plant, consisting of boilers, engine and 1250-kw generator, is capable of supplying twice the amount of power required in the mill, but the capacity of the pump is not much greater than the steady mill demand of 8000 gal. per minute. Water is raised a total height of 255 ft. above the lake, being delivered through a 10-

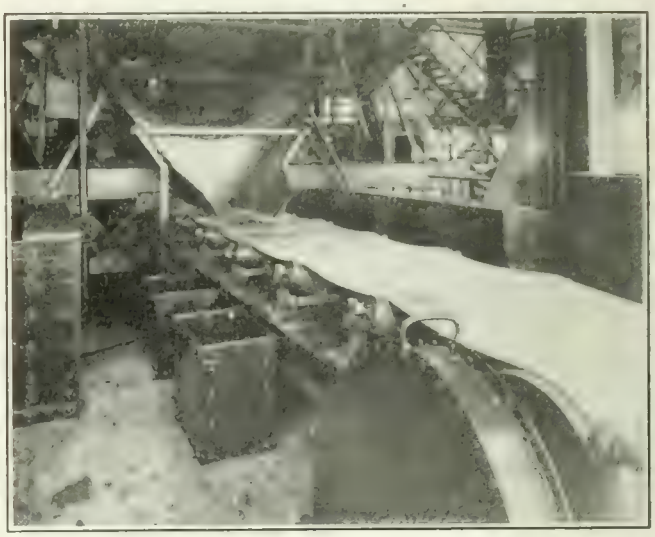

FIG. 5.—PICKING BELT BELOW SCREEN, NASHWAUK PLANT, WISCONSIN STEEL COMPANY.

in. pipe-line to a 110,000-gal. tank erected on a steel structure near the mill. The tank is in no sense a storage reservoir as it holds only about 15-minutes supply, but simply provides the necessary head of water for the mill.

Wisconsin Steel Company's Mill at Nashwauk.

The second iron-ore concentrator built in Minnesota was erected by the Wisconsin Steel Company, to treat ore from the Hawkins mine at Nashwauk. With the exception of some changes, which will be noted, it was modeled after the Trout Lake mill, in which a test run of 1000 tons of Hawkins ore was made, to see what results could be obtained. The two main points of difference are in the method of delivering the crude ore to the head of the mill, and in the extent to which fine concentration is carried. In the Nashwauk mill, Fig. 3, the ore is elevated from the railroad ore-pockets by means of a belt conveyor, passing then through a concentrating system similar to that at Trout Lake, except that no concentrating tables are used.

By reference to Fig. 3, it will be seen that ore is delivered by railroad to two ore-pockets of 250-tons capacity. Below the pockets are shaking launders arranged to deliver to a common point. In operation they discharge alternately onto a 3-ft. rubber-belt conveyor set at an inclination of 19 deg. The conveyor is about 150 ft. long and discharges ore onto a 6-in. grizzly at the head of the mill at a point corresponding to the mouth of the crude-ore bin in the Trout Lake mill. The head pulley of the conveyor is discernible in the upper part of Fig. 3.

The operation of the shaking launders is controlled by one man at the ore-pockets, and the movement of the belt conveyor is governed by the men at its upper end, whose duty it is to sort out waste rock and break large lumps of ore which will not pass the grizzly. Should it become necessary to stop the belt, the man at the feeders is signalled by an electric bell, and the feed is temporarily stopped.

The advantages claimed for this system are: First, that it avoids the construction of the long approach required to deliver carloads of ore to the head of the mill; and second, that a more regular feed is insured by eliminating the possibility of sudden rushes of great masses of ore, which sometimes occur in a large bin. Irregularity of feed, of course, subsequently affects the efficiency of the screen and the log-washers, as well as the quantity and grade of concentrate produced.

The decision to omit the concentrating tables in the Nashwauk mill was determined by the fact that only 3 per cent additional recovery could be made by their use; and the ore thus recovered, being fine, would be the least desirable of all the concentrates. When dry it would practically be dust, subject to loss in transportation as well as in the blast furnace, and altogether hardly worth the outlay of capital and operating expense for fifteen or twenty tables.

With the exceptions noted, the concentrating system at Nashwauk is practically the same as at Trout Lake. A minor difference is the use of small grizzlies instead of chip-screens to remove large particles of lean ore and rock from the overflow of the log-washers to the turbo-washers. The punched plates in the conical screen show about the same life as at Trout Lake. When the blades of the log-washers are worn thin, they are not removed, but are patched with pieces of white-iron bolted to the worn blades. The white-iron blades last from five to six weeks.

All concentrates are delivered to the same bin, and in order to mix the coarse and fine, a part of the stream of log-concentrate is diverted to the launder carrying turbo-concentrate befor the latter enters the bin. The ailing flows out of the mill through an elevated launder which discharges onto an area of low land where the solid tailing accumulates, and the water drains back into the small lake near which the mill is built.

Concentration Results.

The ore treated at Nashwauk is higher grade than at Trout Lake, and the product is proportionately of better quality. The crude will average 40 to 45 per cent iron and 15 to 16 per cent silica. The mixed concentrate averages 60 to 62 per cent iron and 3 to 6 per cent silica. Phosphorus is about two points higher in the concentrate than in the crude ore. It has been found profitable for the purposes of this company to concentrate crude ore containing up to 56 per cent iron. Eighty per cent of the iron in the crude ore is recovered, and the concentrate represents about 62 per cent by weight of the crude ore. Of the total product, 10 per cent is lump concentrate from the conical screens and picking belt, 80 per cent coarse concentrate from the log-washers and 10 per cent fine concentrate from the turbos. Sampling is done twice daily, all the concentrates being temporarily diverted to a steel bin provided for this purpose.

Steam-electric power is generated by a Parsons turbine and 500-kw generator, which gives power greatly in excess of the 125 kw required in the mill. The main unit is operated by a 100-hp motor, as at Trout Lake. The belt conveyor consumes about 30 hp and the shaking feeders about 10 hp. A Prescott steam pump of 2500 gal. per min. capacity supplies water to the mill, the consumption being only 1200 gal. per min. This is proportionately less than is used at Trout Lake, due largely to the omission of the tables.

Iron-Ore Concentration a Recent Development.

The mills described are in operation only six months in the year, corresponding to the regular shipping season on the lakes. The Trout Lake mill has finished its third season, and the Nashwauk mill its first. It is interesting to note that both mills far exceeded their rated capacities, practically by 100 per cent, and have given fully as good results as were anticipated. The Nashwauk mill was planned as a two-unit plnt, but the single unit has proved ample for present needs, and the second may not be installed. As much as 8000 tons of ore has been treated in this unit in one day of 20 hours.

At Coleraine, Mr. M. H. Godfrey is general superintendent for the Oliver Iron Mining Company. Mr. Wm. Nicholls, who is superintendent of the Trout Lake mill, was formerly engaged at some of the large Western copper concentrators. Mr. C. J. Mott is assistant superintendent. The Nashwauk mill is under the management of Capt. Sellwood, of Duluth. Mr. B. W. Batchelder, of Nashwauk, is superintendent.

Problems in the Manufacture of Chemically Pure Acids.*

By J. T. Baker.

The manufacture of chemically pure acids, hydrochloric, nitric, and sulphuric, is a subject concerning which very little if any literature is to be found. The reason for this is mainly that the manufacture of acids which will pass to-day as chemically pure is limited to comparatively recent years and the methods of manufacture have not yet found their way into chemical publications and textbooks.

Twenty-five or thirty years ago the yearly production of chemically pure acids probably did not exceed one month's production at the present time, and owing to the enlarged field

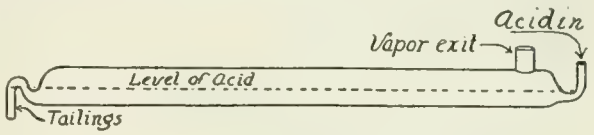

FIG. 1.—IDEAL STILL.

of analytical chemistry, the demand is constantly increasing. The manufacture has now reached a volume which entitles it to be classed as one of the large industries of the country and there are several manufacturing plants devoted in part, if not altogether, to this particular branch of chemical industry.

As a result of the growth of the business, manufacturers have been stimulated, if not obliged by reasons of competition, to devise improved methods of manufacture, in consequence of which the cost of production has been materially reduced and the market prices have fallen during the period mentioned from 50 to 85 per cent. In this connection it is interesting to note some of the improvements which have been made, and

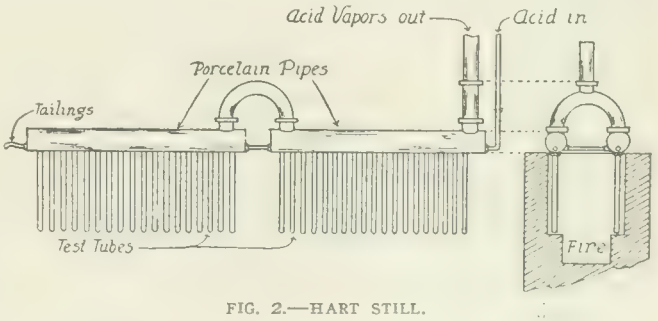

FIG. 2.—HART STILL.

the ingenuity which has been displayed in overcoming some of the almost insurmountable difficulties.

The improvements referred to and to be herein described relate only to the methods of purifying so-called commercial-

* A paper presented before The American Institute of Chemical Engineers. Specially abstracted from vol. IV of The Transactions of the Institute.

grade or crude acids and not to the actual manufacture of the acid itself, the latter being made by the usual methods more or less familiar to every student of industrial chemistry.

There is doubtless plenty of literature on the chemistry of making pure acids, but the chemistry is generally the simplest part of the problems of industrial chemistry, particularly when working on a large scale, for the greatest problems encountered are generally the mechanical details and cost of production.

It is only within the last score of years that the industry has advanced beyond the laboratory scale both in its methods as well as in the volume of its output. For many years the distillation of the crude acid was performed in glass retorts or flasks of 2 or 3 gal. capacity connected with small Liebig condensers in practically the same manner that distillations are performed in a college laboratory, only on a larger scale, and the amount of labor involved, together with the loss from

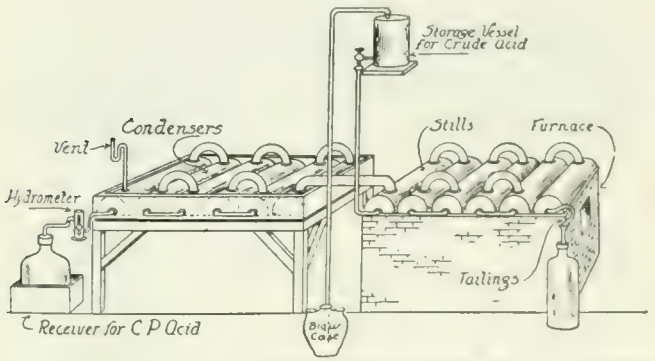

FIG. 3.—DISTILLING AND CONDENSING SYSTEM OF J. T. BAKER CHEMICAL COMPANY.

breakage, made the cost of production not only high but uncertain. It was an interesting sight to see a battery of, say, twenty or thirty retorts side by side on a long sand-bath, each one having a separate condenser with numerous water pipes and stop cocks, all boiling at once; but when one retort accidentally cracked, followed probably by half of the whole battery and the contents suddenly disappeared in a dense cloud through the ventilators of the roof, the sight was rather disheartening.

The great problem was to device a still of small capacity, but with a large heating surface which could be operated continuously by supply crude acid as rapidly as the distillation proceeded, so that the quantity of acid in the still at any one time should never be very great and consequently little lost in case of breakage. Another advantage to be gained by such an arrangement would be the saving in time in getting the distillation started, as there would be but a small volume of liquid to be heated, while in a large still much time is lost in bringing the contents up to the boiling point, not to mention the loss of heat by radiation from the sides of a large vessel.

One great difficulty, however, connected with such still is the necessity of removing the impurities remaining in the tailings, which if allowed to become concentrated beyond a certain point will cause trouble by crystallizing out or spurting and being carried over into the distallate, while if an arrangement is made to draw off the tailings either continuously or intermittently, when using a still of the ordinary compact form, such as a retort or flask, much good acid is liable to be wasted.

An ideal still that will solve the problem is illustrated in Fig. 1, and consists of a long glass tube with an opening at one end to admit fresh acid and one at the other end to draw off the tailings, the openings being in the form of traps to prevent the escape of the vapors, for which an exit is provided near the end at which the acid is admitted.

The still is kept about half-full and is heated from underneath along the entire length, the greatest heat being at the end near the exit of the tailings. The still being long and narrow there will be a constant movement of the contents toward the outlet, at which point the impurities will collect and will gradually be drawn off with the tailings at a rate that will avoid any trouble from crystallizing or spurting. Even if spurting should occur at this point it is so far from the exit for the vapors that there is no danger of any of the impurities being carried over into the distillate. With a constant supply of fresh acid entering the still to replace the contents as rapidly as it distills off, the distillation may be kept up indefinitely.

Such a still as the above, while perhaps practicable as a laboratory experiment, would not answer for operating on a large scale, because owing to the fragile nature of the material available for the purpose, it is not possible to construct such an apparatus that will be durable. The same principle involved has, however, been worked out successfully in various other ways and some of the apparatuses designed are protected by patents.

One of the original inventions was known as the Hart system and one which has proved to be as efficient as it was ingenious, is constructed of glass test tubes. The apparatus is illustrated in Fig. 2. A porcelain vessel in the form of a pipe, say, 4 ft. long, 6 in. diameter, is made with a row of openings close together along one side, into which glass tubes closed at one end and similar to a test tube, say, 18 in. long by 1½ in. diameter, are inserted and the joints made tight with rubber gaskets or asbestos fiber. The vessel is provided with a

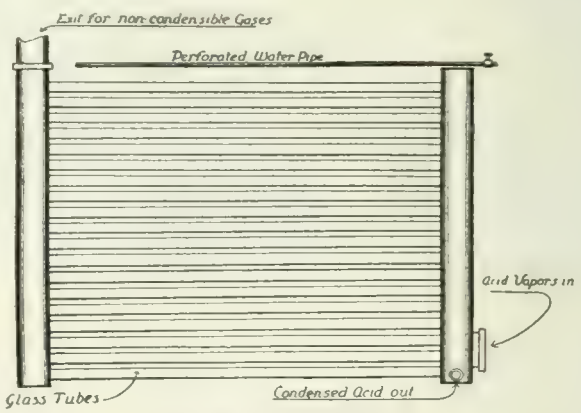

FIG. 4.—HART CONDENSER.

small opening at each end, one for the supply of fresh acid and the other for drawing off the tailings, and a larger opening on top to carry off the vapors. The vessel is supported on the brickwork of the furnace with the glass tubes depending downward and exposed to the direct heat of the fire.

A number of such apparatuses may be connected together and are placed on a level so that when the acid is admitted it will by seeking its level be at the same depth in each vessel and on a level with the outlet for the overflow of the tailings. The boiling takes place in the glass tubes, which afford large heating surface, and the distillation is exceedingly rapid, but may be easily controlled by regulating the temperature of the fire. The durability of the tubes depends upon the quality of the glass, but, as a rule, they stand the strain well and with proper care on the part of the operator the apparatus works quite satisfactorily. If occasionally a tube breaks, it can be replaced with comparatively little trouble without taking the apparatus apart, and the quantity of acid lost is trifling because there is so little in the apparatus that can run out.

When working steadily the still is very efficient, a battery of four having a capacity of about 2000 to 3000 lb. of distillate per twenty-four hours, and if facilities are provided for supplying the acid to the stills by gravity so as to avoid unnecessary handling, the labor involved will be a comparatively small

item of expense, while the loss in breakage and the cost of fuel is reduced to a minimum. This invention has been patented.

Another system of still constructed on the same principle of continuous operation and one which has been used for a number of years by the J. T. Baker Chemical Company is made entirely of porcelain, and having less joints there is less liability

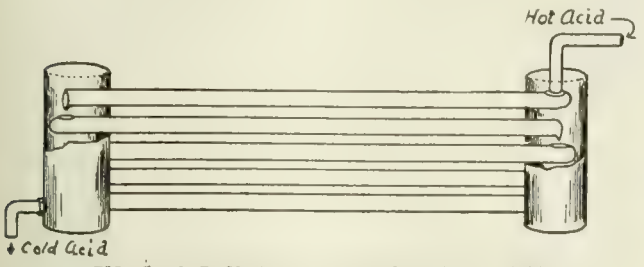

FIG. 5.—BLEACHING AND COOLING APPARATUS.

of leakage than in the apparatus above described, particularly where the joints must be made with asbestos, as in the case of nitric acid.

Under certain conditions porcelain will withstand the strain of great heat better than glass, and it has been found feasible to distill acid from porcelain vessels of considerable size without danger of breakage. An apparatus of this construction is illustrated in Fig. 3 (which, by the way, also illustrates a condensing system to be referred to later).

The vessels measure about 3 ft. in length by 8 in. in width and are flat on the bottom in order to obtain a large heating surface. A number of vessels, say 10, are laid side by side on top of the furnace directly over the firebox and are connected together with small glass tubes near the bottom to conduct the acid through each vessel in succession and with porcelain goose-neck pipes for the passage of the vapors. The large extent of heating surface which the vessels afford makes the apparatus a very efficient still without forcing the fire and running the risk of cracking the porcelain, which owing to the size and nature of the ware has comparatively thick walls. In order to avoid condensation in the stills owing to the radiation of heat from the upper surface, the vessels are protected with a covering of asbestos. The joints are packed with rubber gaskets for hydrochloric acid and with pure asbestos fiber for nitric acid.

The crude acid is first elevated by air pressure from a blow case located where it can be filled conveniently to a storage vessel overhead from which it runs by gravity into the stills, the flow being regulated by a cock so that there will be a slight overflow of the tailings at the farther end of the system. The capacity of the still is about 2500 lb. hydrochloric acid and 4000 nitric acid per twenty-four hours' continuous running.

The condensation of acid vapors on a large scale was also a serious problem, for an efficient condensing system is absolutely essential to the successful working of any still. One of the first efficient condensers invented and patented was constructed of glass tubes and is illustrated in Fig. 4.

It consists of a number of glass tubes 6 or 7 ft. long by 1 in. diameter, and two so-called standpipes made of earthenware or porcelain (the latter especially for chemically pure acids), each about 4 ft. long by 4 in. diameter, having a row of holes along one side as close together as possible and of a suitable size to receive the glass tubes without binding. The standpipes are placed in an upright position and securely fastened in place, having the rows of holes facing each other and at a distance that will allow the tubes to enter far enough to enable the joints to be tightly packed. The acid vapors enter through an opening in the side of one of the standpipes and is divided in its passage through the tubes in which the condensation is effected by trickling cold water on the surface of the tubes supplied from a perforated water pipe placed just above the topmost tube; the water trickles down over each tube in succession and becomes so hot before it reaches the bottom that much of it evaporates, thus increasing the efficiency of the condenser, and what does not evaporate is caught in a trough and carried off. The glass tubes are subjected to the extremes of temperatures where the cold water first strikes, but with a good quality of glass they stand the strain remarkably well, although breakage is not infrequent.

Condensation may also be effected without the use of water, as the heat radiates to considerable extent and causes a current of air which carries off the heat by contact. The cooling effect of the air is, of course, not as effective as that of water, but this deficiency may be made up by increasing the number of tubes. This also removes the danger of breakage experienced when using water, but, on the other hand, it increases the number of joints and the liability of loss from leakage when asbestos is used as a packing.

This condensing system, known as the Hart condenser, from the name of the inventor, has been in successful operation during a number of years as a condenser for both nitric and hydrochloric acids with certain modifications to suit the peculiarities of each acid, which will be referred to later.

The condensing system used by the J. T. Baker Chemical Company is made entirely of porcelain vessels and is illustrated in Fig. 3, previously referred to. The vessels are made practically the same as the porcelain vessels used as stills and are connected together in the same manner for the flow of the acid and the passage of the vapors. The condensation is effected by immersing the vessels in a bath of running water, the flow of the water being regulated so that the water surrounding the vessel into which the hot vapor from the still is entering will not be subjected to too great a change of temperature, otherwise breakage is liable to occur owing to the size of the vessel and the thickness of the walls. There are comparatively few joints to cause trouble from leakage, and they are easy to get at and keep tight. They are used for

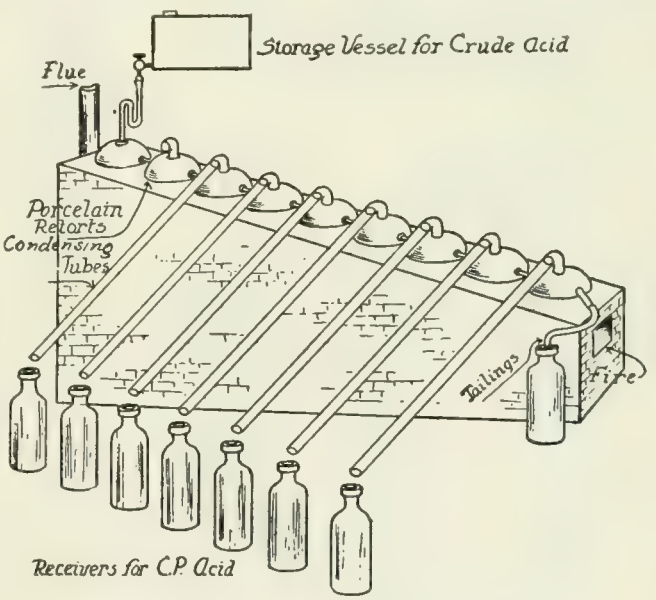

FIG. 6.—CONTINUOUS STILL SYSTEM OF J. T. BAKER COMPANY.

condensing both hydrochloric and nitric acids with some modifications to suit the peculiarities of each acid, the modus operandi of which will next be described.

The distillation and condensation of hydrochloric acid present difficulties which are peculiar to the acid itself and give rise to problems different from distillation processes in general. This is due to the fact that the concentrated acid does not distill at a uniform degree of strength nor at a uniform temperature. The strongest acid commences to distill at a very low temperature and gives off at first dense fumes of dry HCl gas which are uncondensable and must, therefore, be absorbed in water or in a weaker acid. As the distillation pro-

ceeds the temperature rises and the strength of the distillate as well as the remaining liquid decreases until both reach a strength of about 1.10 sp. gr., after which the strength of both, as well as the boiling point, remain constant.

The weaker grades of acid must, therefore, be again concentrated by saturation with the gas from subsequent distillations, and as the absorption gives rise to heat it becomes necessary to change the receivers frequently and allow them to cool in order that the final saturation may be made at a temperature low enough to insure the proper degree of strength. This was the old method of distilling, and, as it was necessary to use comparatively small stills, generally flasks of 2 or 3 gal. capacity, each one connected with a small Liebig condenser, and receivers of about the same capacity, the process involved much

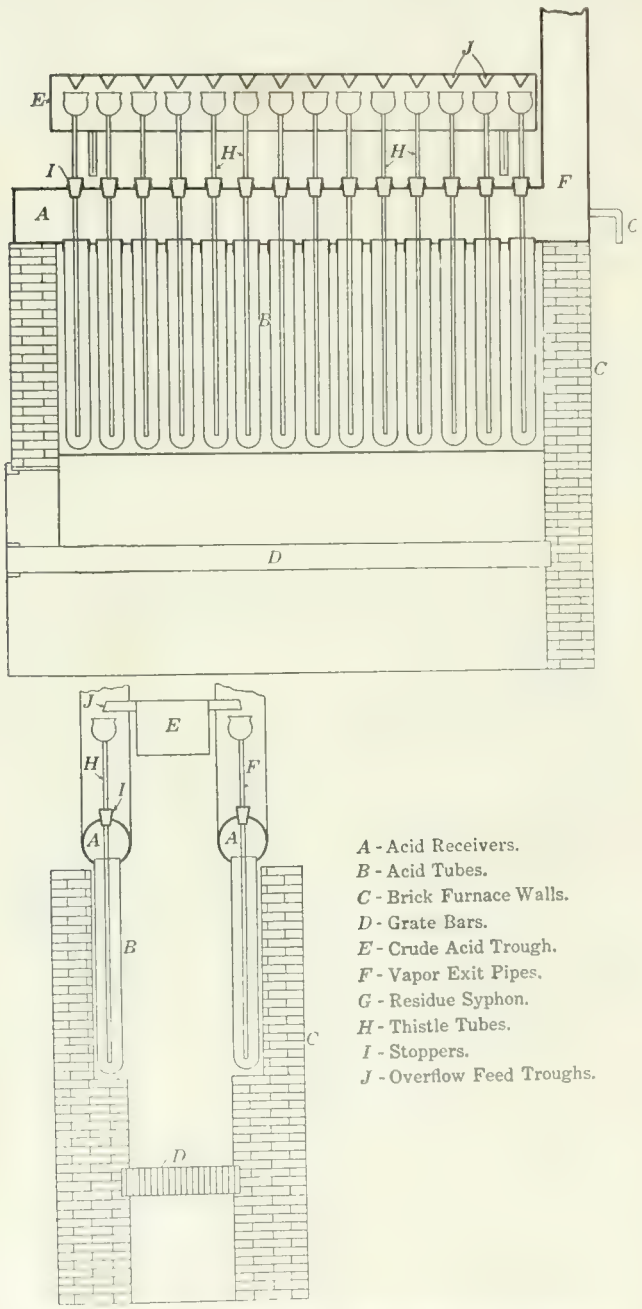

FIG. 7.—IMPROVED APPARATUS FOR DISTILLING APPARATUS.

labor and was far from being economical, particularly when attempting to work on a large scale.

These difficulties were all successfully overcome when the continuously operating system was introduced. In this system the distillation of the strong and the weak acid takes place at the same time and the different strengths passing into the condenser together at once recombine, the gas being absorbed in the liquid simultaneously as the vapors condense, and the acid when it finally leaves the condenser will have the same strength as the acid entering the still. In the first vessel of the distilling system into which the fresh acid enters there is presumably a slight ebullition and dry gas given off, while from each succeeding vessel down to the last ones situated directly over the fire there is more or less moisture given off with a corresponding decrease in the strength of the tailings, the weakest being about 1.10 sp. gr.

In the first vessel of the condensing system into which the vapor enters (referring to the system illustrated in Fig. 3) only the weakest vapors condense, while owing to the temperature of the water surrounding the vessel being almost the same as that of the vapors, the gas passes on into the cooler vessels where it is absorbed by the liquid flowing slowly through them until in the last vessel, which is thoroughly cooled, the gas is all absorbed and the liquid at the same time saturated. The

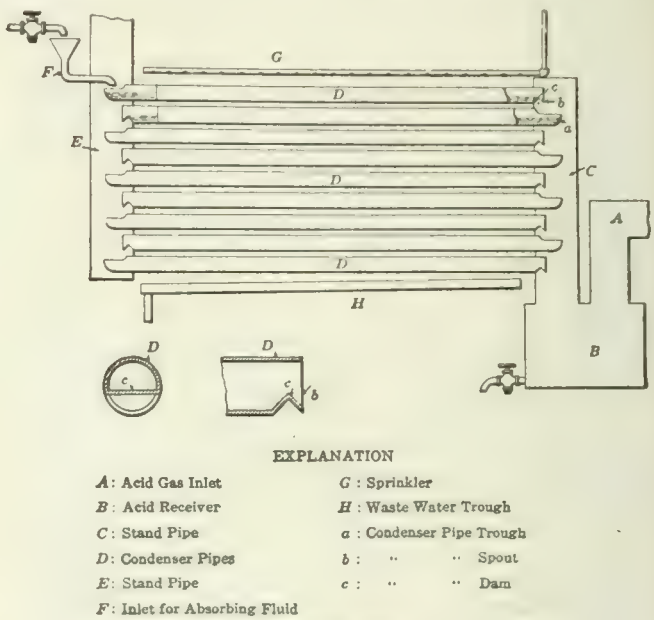

FIG. 8.—HYDROCHLORIC ACID CONDENSER, HART-ADAMSON PATENT.

acid runs by gravity from the last vessel through a jar containing a small hydrometer and enables the operator to keep watch of the strength, which varies according to the proportion of tailings drawn off.

The distillate is usually a little stronger than the original acid owing to the removal of the tailings, for the reason that as the acid entering the still contains, say, 36 per cent HCl, the tailings contain only about 20 per cent, and the difference in the amount of HCl gas is absorbed in the distillate, thereby increasing the strength to that extent. Indeed it is possible, by drawing the tailings off faster, to bring up the strength of an acid which is 2 or 3 deg. below saturation before distillation, but the method is not economical; the best results are obtained by using an acid, say, 1.18 sp. gr. and drawing off enough tailings to bring it up to 1.19 sp. gr., which is the strength generally required by the trade. About 5 per cent in tailings is sufficient for this purpose and this amount is also sufficient to carry off the impurities fast enough when using ordinary commercial hydrochloric acid.

The impurities commonly found in the commercial acid are principally sulphuric acid, iron, sodium sulphate, arsenic, and sometimes sulphurous acid and free chlorine. Before distilling the acid sufficient chlorine is added to oxidize the H_2SO_3 to H_2SO_4, the excess of Cl being reduced by adding some reducing salt in solution. The non-volatile impurities remain in the tailings, and if there is any spurting in the last vessel where they become concentrated, or any volatilization of sulphuric

acid at this point, these impurities will be retained in the other vessel without danger of being carried over into the distillate. Arsenic compounds being volatile are always found in the distillate, at least in traces, as it is impossible to obtain a crude acid made in the ordinary way from salt and sulphuric acid which does not contain some of this impurity.

An acid made synthetically from Cl and H as a by-product in the manufacture of caustic potash at Niagara Falls is free from arsenic and a chemically pure acid made by distilling this product after reducing the free Cl, which is always present in great excess, is strictly chemically pure. Organic matter is difficult to remove, as it appears to form a volatile organic chloride which distills over and gives a yellow color to the distillate, although it can then be reduced and removed by a second distillate.

Hydrochloric acid can also be condensed in a glass tube apparatus similar to one above described (Fig. 4) with some modifications; the tubes instead of being open at both ends are closed at one end and an opening made on the upper side when in a horizontal position placed directly under the open end of the tube above, which is provided with a lip, so that when arranged in alternate order the liquid will flow from the topmost tube through each tube in succession to the bottom. In this way the vapors which condense in the tubes follow a long and tortuous passage over which the gas passes and is gradually absorbed, while at the same time it is kept cool by water trickling over the outside. This arrangement is illustrated in Fig. 5, where it is described for another purpose. As an apparatus for absorbing gases it is covered by patents.

In the distillation of nitric acid difficulties are met which are easily overcome by using a continuously operating system similar to that used for hydrochloric acid with some modifications. The impurities commonly present in the crude acid are sulphuric acid and sodium sulphate from the materials used in its manufacture, chlorine and iodine present in the nitrate of soda and hyponitric acid due to a slight decomposition of the nitric acid in the process of manufacture.

The chlorine and hyponitric acid are volatile at a low temperature and will, therefore, be found in the first part of the distillate; the balance of the distillate will, however, contain some hyponitric due to a slight decomposition of the acid giving the distillate a slight yellow color, which can be removed by heating and subsequent exposure to air. In a continuously operating still, such as either of those above described, the volatile impurities are separated by conducting the vapors from the first vessel or two to a separate condenser from that in which the vapors from the remaining vessels are condensed, and instead of allowing the acid to leave the condenser cold, the latter is constructed so that the acid is drawn off hot in order to bleach it without subsequent heating. This is accomplished when using the glass tube condenser, by giving the tubes a slight inclination towards the standpipe into which the hot vapors are entering, and when using the porcelain vessel system, by inclining the bath and reversing the flow of the condensed acid back into the first vessel, in each case forming a sort of reflux condenser. The hot acid thus obtained is led through a bleaching apparatus which also serves as a cooler to reduce the temperature and avoid cracking the receiving vessel. This apparatus is illustrated in Fig. 5.

As previously described it consists of a number of glass tubes constructed so that the acid flows successively through all the tubes and being thus exposed to the air which is carried along with it, the hyponitric acid is oxidized and at the same time the heat is absorbed by trickling cold water on the outside of the tubes in the usual manner. Furthermore, if the acid is above standard strength (sp. gr. 1.42), as is generally the case when crude acid is made solely for redistilling, the strength may be reduced by adding a calculated quantity of distilled water while it is running through the cooler, which also removes the heat thus generated.

This distillation of sulphuric acid presents a more difficult problem than the other acids on account of the high temperature at which it boils. Glass retorts with very thin walls have generally been found the only thing suitable, although it is well known that porcelain vessels have been used in concentrating chamber acid by distilling off the water and bringing it up to a strength somewhat below complete concentration, a process which, of course, does not require a temperature as high as the distribution of the concentrated acid itself.

After experimenting for some time, a method for using porcelain retorts was devised and a continuously operating system of stills made of this ware is now being successfully used by the J. T. Baker Chemical Co. The stills or retorts are made comparatively small and hemispherical in shape, being about 8 inches in diameter across the bottom. On each side are tubular openings of suitable size so that the retorts can be connected together by passing the tubular of one retort into the tubular of the retort next to it. Instead of having the retorts on a level as in the other systems, they are laid on an incline as shown in Fig. 6, so that the acid overflows from one retort into the next below, the position of the outlets being such that the acid stands at the depth of about 2 inches in each retort. The joints are packed with asbestos to prevent the escape of vapors, and the upper parts of the retorts are protected to prevent the radiation of heat.

The fire is located at the lower end of the furnace with a long inclined flue over which the retorts are laid and the waste heat utilized for bringing the acid up to the boiling point before it reaches the point where the distillation takes place. A number of retorts can be placed on one furnace, and from about half of them nearest the lower end concentrated acid will be obtained, the others giving acid containing more or less water. The crude acid is supplied in a steady stream and is regulated so that there is a constant overflow of tailings from the last retort.

The impurities in crude sulphuric acid are principally sulphate of lead and sulphate of iron, and if present in any great quantity will give trouble by forming incrustations on the bottom of the retorts and cause bumping and breakage, unless the retorts are cleaned out at regular intervals of four or five weeks' steady running.

The condensation of sulphuric acid vapors may be effected in glass tubes without using water to absorb the heat, provided the tubes are long enough, say 7 ft. long by 1 in. diameter. Owing to the high temperature of the vapors the strain on the glass is very great, but with a good quality of glass having very thin walls this method of condensation has proved quite successful in the past, notwithstanding that breakage was a frequent occurrence, particularly in cold weather. The condensation, however, was seldom complete and there was more or less escape of acid fumes from the ends of the tubes, while the temperature of the condensed acid was very little below the boiling point, so that the receiving vessels, which were necessarily made of glass, were frequently cracked. The constant escape of irritating fumes and the danger to the operator from handling the hot acid added to the difficulties which made the problem of condensation a serious one.

The introduction of fused silica ware has helped to solve this problem, for owing to its great resisting power to changes in temperature, it is possible to use silica tubes in place of glass and sprinkle them with water. This not only effects a complete condensation of vapors, but reduces the temperature of the distillate to a point at which it can be handled with perfect safety.

* * *

In the discussion which followed Prof. **Edward Hart** spoke of his own work in this field. As to the glass flasks mentioned by Mr. Baker, he said that they found them very unsatisfactory since they broke frequently and required a great deal of coal. In consequence of this he (Prof. Hart) devised the hanging test-tubes (Fig. 2) and they found that one-sixth of the coal formerly used was sufficient.

Prof. Hart thought that the apparatus of Mr. Baker, made of porcelain, would probably not be so economical of coal as the Hart apparatus with the hanging test-tubes. A patent for a modification of the hanging test-tubes has been applied for which is an improvement on the old form. In the old form the circulation in the tubes was very poor, so that sulphate of soda was apt to accumulate and finally break the tube; but this was obviated by the modification shown in Fig. 7, in which A is the acid receiver, B the hanging tubes, J a trough for the supply of acid and H thistle tubes feeding the acid to the bottom of the hanging test-tubes. The object of the introduction in this way is obvious, since the fresh acid is fed to the bottom of the hanging tube and the strong residues containing the sulphate of soda are forced through G. In case of hydrochloric acid the I stoppers are made of rubber.

Dr. **F. W. Frerichs** said that in the last twenty years he has manufactured large quantities of chemically pure acids, using 5-gallon glass retorts, each retort set in a small iron kettle. Nitric acid simply was distilled. Hydrochloric acid was distilled from crude acid after treating it in such a manner that free chlorine and sulphurous acid would not contaminate the product. They would obtain, at the end of the distillation, a very weak acid which was condensed in large 5-gallon glass receivers, and they ran water over the body of the receivers to effect cooling. Taking weak hydrochloric acid from one operation and saturating it with hydrochloric acid gas coming off first in the following operation, they obtained strong acid. For the manufacture of chemically pure sulphuric acid, they bought weak sulphuric acid 20 Be. coming from platinum stills. Strong acid was obtained by evaporation of pure weak acid. This was a very slow process, but made upwards of 200,000 lbs.

Mr. **J. T. Baker** said he felt that he owed it to Prof. Hart to say that his inventive genius had been stimulated by the association he had with Prof. Hart. As to the Hart still, he believes it is a very excellent form of still, but owing to the fact that this was covered by patents, he was compelled to make a substitute. Porcelain stills make a very good substitute.

Prof. **Edward Hart** called attention to an ingenious device of Mr. Adamson for the absorption of hydrochloric acid. The arrangement of condensing tubes in this is Hart's. The little dam made in the end of the tube, shown in Fig. 8, is Mr. Adamson's invention. By this simple device the liquid is retained in each tube for some time, allowing a much more perfect absorption than could otherwise be had. They have found this a very efficient apparatus.

In reply to a question by Mr. Minor, whether there is any preheating of the acid, Mr. Baker said that it is not really necessary. It is merely preheated by being in the flue of the fire. The fire does not cover the entire portion of the still. The fire will probably be in the first part and the other tube will be in the flue. They used that in distilling nitric acid, because it could be distilled at a low temperature.

Alloy Research of Bureau of Mines.—The United States Civil Service Commission announces an open competition examination for alloy chemist, for men only (salary ranging from $2,400 to $3,000 per year), and another for junior alloy chemist, for men only (salary ranging from $1,500 to $1,800 per year) in the Bureau of Mines, Department of the Interior. The duties of the former position will consist of "an investigation covering the methods of preparing non-ferrous alloys, the furnaces and other appliances used in their manufacture, and the prevention of waste in their production." The duties of the junior alloy chemist will consist of assisting in this investigation.

The **Braden Copper Company,** of Chili, has given the Hardinge Conical Mill Company an additional and repeat order for twelve more 8-ft. Hardinge pebble mills, making a total of sixteen mills.

British Institute of Metals.

The annual autumn meeting of the British Institute of Metals was held in London on September 25 and 26. The papers presented at this meeting are herewith abstracted.

"The Annealing of Coinage Alloys" was discussed in a paper by Dr. **T. Kirke Rose.**

The softening caused by annealing the pure metals gold, silver, copper, nickel, etc., and the alloys used in coinage was studied with the aid of the scleroscope, an instrument by which the hardness of metals is measured.

The metals and alloys hardened by rolling were annealed at various temperatures for lengths of time, ranging from a few seconds to 16 days. It was found that at moderate temperatures annealing begins almost imperceptibly. As the temperature rises this change is hastened until, at much higher temperatures, metals and alloys revert from the hard to the soft state instantaneously.

For example, pure gold can be softened in about 100 hours at 100 deg. C., in one hour at 150 deg. C., and in a few seconds at 200 deg. C. At lower than 100 deg. C. more time is required. Lead softens instantaneously, and zinc, cadmium and tin gradually at 15 deg.

Alloys generally require a higher temperature for annealing than their constituent metals. Thus, standard gold can be annealed in 16 days at 300 deg., and in a few seconds at 600 or 700 deg. Full details of all the coinage alloys are given.

Softening is accompanied by recrystallization, the large distorted primary crystals in the hardened metal being broken up into microscopic ones. Recrystallization takes place instantaneously if the softening is instantaneous.

The chief practical conclusion to be drawn from the investigation is that the time of annealing may be made very short if the proper temperature in each case is attained.

The paper is illustrated by curves and photomicrographs.

"The Effect of Temperatures Higher Than Atmospheric on Tensile Tests of Copper and Its Alloys" was discussed in a paper by Professor **A. K. Huntington,** summarizing in 32 curves results obtained at various times during the last 12 years.

The range of temperatures given in this paper is restricted to such as might occur during the use of these metals and alloys in the arts, as distinguished from the temperatures at which they are worked.

The method by which the data were arrived at is also described in detail. Very pure electrolytic copper is taken as a standard for comparison, and first of all various copper alloys are contrasted with it. Broadly speaking, the alloys are found to have the same characteristics as the pure copper. Contrary to what might have been expected, copper is the dominating partner. It has a distinct individuality which is modified, but not extinguished, by the other metals. The curves for wrought iron and steel are compared with those for copper, and it is shown that the former are markedly different from the latter.

As a result of having to consider generally only cold tests of iron and steel, engineers are in the habit of reckoning the elastic limit as 50 per cent of the breaking load. It will be seen from the curves given in this paper that this method of estimating the elastic limit is not correct for iron and steel at temperatures above the normal, nor, as a rule, for other metals at any temperature.

It is fairly certain that engineers have hitherto expected a reduction of elongation with an increase in the breaking load in a given metal or alloy. They have been justified in this by the behavior of iron and steel at atmospheric temperatures, and they are still justified at such temperatures, as these metals are used in the arts. That they are not justified in applying this rule to copper and its alloys is manifest from an examination of the curves in this paper.

"Inter-Crystalline Cohesion in Metals" was discussed in a paper by Dr. **Walter Rosenhain** and Mr. **Donald Ewen,** both of the National Physical Laboratory.

The authors accept as the most reasonable explanation of the special strength possessed by the crystal boundaries of metals in a normal condition the existence of an inter-crystalline cementing material, and in their present paper certain experiments and considerations are described which lend considerable weight to their hypothesis that this cementing material consists of the metal itself in an amorphous condition, a conception which has been arrived at by several investigators quite independently. Further, they explain the presence of this amorphous material by assuming that what they term a "crystal unit" depends for its formation on the grouping together of several previously existing "liquid" molecules, and that when two or more crystal systems abut against one another a series of interstices result which are smaller than the "crystal units," and in consequence the liquid in them is unable to take up its crystalline form.

The production of inter-crystalline brittleness in metals by suitable heat treatment and the adaptation of a metal to strain at high temperatures by the abnormal development of the inter-crystalline boundaries rather than by the formation of slip-bands, are phenomena among others which have been observed by the authors in their laboratory, and which are quite consistent with their hypothesis.

Beilby has shown that metal in the amorphous condition is more soluble and generally more chemically active than when crystalline, and it seemed reasonable to the authors to suppose that it might also be more volatile and that if two specimens of metal—one in a finely crystalline form and the other coarsely crystalline—were subjected to the same vacuum and temperature for the same period of time, the former would lose weight more rapidly than the latter, owing to the total area of inter-crystalline boundary being greater. Experiments carried out with silver, copper and zinc, heated in high vacua to temperatures about 100 deg. C. below their melting points have entirely confirmed this expectation, definite and constant ratios of loss of weight per unit area between the coarse and fine specimens being found, thus for zinc of at least 99.8 per cent purity the ratios fine-coarse in three independent heats with the same specimens were 2.25, 2.26 and 2.37. In the case of silver the ratios in five independent heats varied from 1.07 to 1.27.

Photomicrographs of the various metals before and after heating are given, and an appendix on the formation of twinned crystals in silver is added.

"The Effect of Other Metals on the Structure of the Beta Constituent in Copper-Zinc Alloys" was discussed in a paper by Professor **H. C. H. Carpenter.**

The influence of various common metals on the structure of the apparent beta constituent in copper-zinc alloys was determined.

Class I.—Metals insoluble in copper or zinc, viz.: bismuth, lead and chromium. With the exception of one alloy, containing 2.9 per cent of bismuth, their effects on the structural stability of apparent beta were found to be very slight, and the conclusion is warranted that the percentage of lead and bismuth ordinarily present in industrial alloys are entirely without influence.

Class II.—Metals of somewhat limited solubility, viz.: iron, antimony, tin, aluminium, silicon and vanadium. With the exception of iron, all these metals aid the precipitation of alpha-gamma visible at low magnifications from apparent beta. They displace the alloy from the eutectoid composition, and shift it to the gamma side. Consequently gamma crystallites are produced, leaving a matrix of alpha. Iron is very much slower in its action, and up to about 2 per cent is without effect. It forms a connecting link between Classes I and II.

Class III.—Metals of great solubility, viz.: nickel and manganese. Nickel is somewhat irregular in its action, but behaves like the majority of the metals in Class II, whereas manganese is almost without action of this kind.

The metals iron, chromium and manganese have only a slight influence on the temperature of the beta to alpha + gamma inversion. No metal has been found capable of lowering this transformation below the ordinary temperature.

The problem of making beta the stable phase at the ordinary temperature appears to be theoretically insoluble. Practically, however, the structural stability of apparent beta can be strengthened by keeping down the impurities in copper-zinc alloys to a minimum.

Provided that such alloys are not heated in use their stability will last practically for an indefinite period.

"The Structural Resolution of the Pure Copper-Zinc Beta Constituent Into Alpha Plus Gamma" was discussed in a paper by Professor **H. C. H. Carpenter.**

The beta structure of the pure alpha plus gamma eutectoid alloy may be regarded as absolutely stable. It cannot be upset by any annealing, however prolonged, and in this respect it appears quite unique.

Repeated quenchings of this alloy in liquid air undoubtedly produce structures characteristic of a two-phase system. These structures, however, are of a transitory nature, and the conditions of their appearance are also obscure. They do not appear to correspond to a segregation of alpha plus gamma in a coarse crystalline form.

Between 460 deg. C. and the ordinary temperature the alloy was found to undergo no other inversion detectible on a cooling curve.

Ultimately the resolution of the pure beta structure into alpha plus gamma was brought about by the "nucleus" action of an eutectoid alloy containing 0.95 per cent of vanadium, which contains its alpha plus gamma in a coarse crystalline form immediately after being cast. By infecting the pure apparent beta alloy with this substance for a short period at 420 deg. C., followed by a prolonged annealing, coarse segregations of alpha and gamma were obtained.

A lamellar resolution of pure beta was never observed.

"The Influence of Oxygen on the Properties of Metals and Alloys" was discussed in a paper by Mr. **Edward F. Law,** dealing with the question of oxides occurring in metals and alloys. The subject is viewed from a general standpoint and is not confined to any particular metal or alloy.

It is pointed out that the existence of these oxides is usually ignored inasmuch as they are not determined in the ordinary course of chemical analysis, and they frequently escape detection by mechanical tests. Nevertheless, they play an important part in the behavior of the metals when in service, and the author contends that they are all the more dangerous on account of the ease with which they may escape detection by the ordinary methods of testing.

Instances are cited of the failure of bearings, the fracture of copper fireboxes and other troubles caused by the presence of oxides. Attention is particularly directed to the influence of oxides on the corrosion of metals, and the author states it as his opinion that experimental work on corrosion which does not take into account the presence of oxides in the metals experimented upon is of little value.

"The Joining of Metals" is discussed in a paper by Mr. **A. E. Tucker.**

The author shows that whereas metals used often to be joined by riveting or folding, these processes are now largely replaced by autogenous welding and other recently introduced means. Methods of joining metals by physical processes, such as welding and brazing, give rise to some interesting considerations, and the physical process involved in such operation, and the commercial application of these operations are detailed in the paper.

The author discusses the phenomena of cohesion and adhesion, stating that when high heats are used cohesion would appear to act, but it is well known that fusion is not required for affecting the union of several metals to bring about a joint having a great degree of strength.

The methods in practical use for joining metals are shown to be by metallic cement, such as tinman's or brazing solder, by autogenous fusion, or by the use of a cementing material under pressure.

The soldering of aluminium has always presented considerable difficulties, and Mr. Tucker discusses this question in detail. He states that if the two surfaces of aluminium are cleaned with a certain flux and an alloy (solder) containing a high percentage of aluminium, with such addition of any metal as will reduce its melting point slightly below that of pure aluminium, is used, it is possible to obtain a satisfactory joint that will stand even the hot steam test.

Other processes dealt with in the paper include autogenous fusion; the oxy-acetylene process; the use of aluminium powder; arc welding and resistance welding, and the manufacture of compound sheets.

"Autogenous Welding by Means of Oxygen and Acetylene of Copper and Its Principal Alloys, and of Aluminium" was discussed in a paper by Professor **F. Carnevali.**

The author describes a series of experiments on a subject of considerable practical importance nowadays, namely, the oxy-acetylene welding of copper, brass, bronze and aluminium. The paper is illustrated by a number of photographs of actual welds and weld fractures, as well as of microphotographs highly magnified in order to illustrate the structure of the welded metals.

Dr. Carnevali shows, in the case of copper and its principal alloys, that rapid heating and sudden fusion of the metals subjected to welding profoundly modify their physical and mechanical properties, developing within them strains and structural alterations which are detrimental to the metal. In the case of copper there is an average reduction of 50 per cent in the capacity to resist fracture, and an increase of about 30 per cent in brittleness, while the percentage of ductility is reduced to about a tenth of the original. In the case of bronzes and brasses it has not been found possible to determine the extent of the deterioration in the mechanical properties, but this deterioration increases as the number of constituents of the alloys subjected to welding are increased. In the case of alloys made up of several constituents, these may be improved after welding by a suitable heat treatment, thus relieving the internal strain set up by the sudden temperature changes involved in the process of welding.

The author maintains that the oxy-acetylene welding of copper and its principal alloys has a practical application limited to those parts of machinery which are not of large dimensions, and which are not subjected to severe mechanical stresses.

As regards the autogenous welding of aluminium, the author observes that the sudden heating and rapid fusion of the metal subjected to the welding process alters the physical and mechanical properties in a manner analogous to that noticed in the case of copper, but to a less degree. The structural modifications principally take the form of coarse crystallization of the metal. His experiments show that both by hammering and by reheating to 450-500 deg. C. the homogeneity of the weld-zone is increased; also that whenever aluminium contains small quantities of other elements easily oxidized at high temperatures, e.g., copper, the oxidization of the metal by fusion is facilitated; also the inclusion within it of granules of oxide detrimental to the mechanical properties of the weld-zone.

Carried out with the necessary precautions, the oxy-acetylene autogenous welding of aluminium is held by Dr. Carnevali to be capable of extensive practical application, especially for the autogenous welding of small machine parts.

"Oxygen in Brass" is discussed in a paper by Professor **T. Turner.** Brass ingots which have been poured at too low a temperature, and metal which has been rolled and annealed, are sometimes brittle and unsatisfactory owing to the presence of oxygen. This oxygen does not appear to be dissolved in the metal, nor to exist in the form of a eutectic, as is the case with copper and copper oxide. Oxide of copper cannot exist in melted brass, as it is immediately reduced by zinc with the formation of oxide of zinc. Oxide of zinc appears to be insoluble in brass and in zinc. The action of the oxide of zinc in spoiling the mechanical properties of brass, appears, therefore, to be merely that of a foreign brittle body or powder which prevents the particles of brass from coming into metallic contact with each other.

The estimation of oxide of zinc in brass presents special difficulties. Experiments are described which show that the methods adopted for the determination of oxygen in copper are not suitable for brass. A ready and accurate process is still required by chemists employed in connection with brass manufacture.

"The Influence of Impurities in 'Tough-Pitch' Copper, with Chief Reference to Antimony," is discussed in a paper by Mr. **F. Johnson.**

In continuation of a series of experiments carried out with a view to ascertaining and placing on record the varied influences of traces of impurities on the useful properties of copper, the author has presented the results of experiments which have been directed toward the determination of the influence on copper of antimony, and, to a lesser degree, of lead and tin.

The experiments have dealt mainly with the modification of the physical and mechanical properties of "touch-pitch" copper brought about by the presence of the above-mentioned impurities. The presence of a certain critical quantity of oxygen is shown in some cases to be absolutely essential to insure good hot-working properties. The following are the conclusions given by the author as a result of the investigation:

1. Antimony up to 0.5 per cent has no detrimental influence on the hot-forging qualities of "tough-pitch" copper free from other impurities. It is even possible successfully to forge copper containing 1 per cent antimony if sufficient oxygen be present.

2. In copper which has been "overpoled," antimony tends to mitigate the phenomenon of "spewing" during solidification.

3. "Tough-pitch" arsenical copper (0.4 per cent arsenic) is slightly hardened for hot-rolling by the presence of antimony (0.2 per cent), but otherwise its mechanical properties are slightly improved.

4. The mechanical properties of "tough-pitch" pure copper after rolling and annealing are but little altered by small additions of antimony. The tensile strength is slightly raised, and the elongation is lowered. The slight gain in toughness is probably traceable to the greater soundness of the case ingot.

5. With regard to the structural condition of antimony in "tough-pitch" copper, it exists in two forms: (a) Partly in solid solution (probably as dissolved Cu_2Sb). (b) Partly as an insoluble compound with oxygen (slate-colored "oxidules"). Oxygen in excess exists as cuprous oxide (light blue "oxidules"). The latter, together with the antimonial "oxidules," form a ternary eutectic with the solid solution.

6. The addition of lead to pure copper or arsenical copper causes the surface of a "tough-pitch" ingot to sink during solidification. Further poling with the object of obtaining a level surface is attended by the risk of rendering

the metal "red-short." Like antimony and arsenic, lead tends to check "spewing."

7. The mechanical properties of arsenical copper (0.4 per cent arsenic) at normal temperature are little affected by the addition of lead (0.2 per cent).

8. The addition of tin (0.2 per cent) to "tough-pitch" arsenical copper is attended by an increase in hardness during hot and cold rolling, and an increase in tensile strength. The elongation is correspondingly lowered, but the toughness is unimpaired.

The Possibilities of a Potash Industry in the U. S.

Papers read before the Eighth International Congress of Applied Chemistry

The Production of Available Potash from the Natural Silicates

Abstract of paper read before the Eighth International Congress of Applied Chemistry.*

By ALLERTON S. CUSHMAN and GEO. W. COGGESHALL.

There is an enormous supply of feldspar in the United States, both east and west, which could be made a source of potash supply, provided the cost of production is low enough to compete with the potash-holding manure salts which are at present so largely imported from Germany. Although the imported potash salts are richer in potash than any product that can ever be made from American feldspar, yet the crude German manure salts contain large quantities of chloride and sulphates of elements which are not only undesirable in the fertilizer, but which may do actual harm under certain conditions. It is this fact which gives encouragement to the attempt to produce from American feldspar a straight potash fertilizer which could be used in exactly the same way that hardwood ashes have been found useful.

The natural silicates commercially available as sources of potash are chiefly orthoclase and leucite. Both of these minerals are potassium-aluminium silicates. The theoretical formula for orthoclase is written $K_2O.Al_2O_3.6SiO_2$ and for leucite $K_2O.Al_2O_3.4SiO_2$. The principal sodium feldspar, albite, has the theoretical formula: $Na_2O.Al_2O_3.6SiO_2$. It is well known that these feldspars run into and substitute each other in various proportions so that the products from different quarries will vary widely in respect to their soda and potash contents.

Six General Lines of Research.

Six general methods have been proposed for decomposing the natural silicates in order to obtain potash salts soluble in water.

I. Adaptation of Natural Agencies like the action of moisture, of carbonic acid gases, etc. In the slow processes of nature these agencies are known to have a decomposing or kaolinizing action upon feldspar.

In 1904 Blackmore (U. S. Patent 772,206) proposed the action of carbon dioxide gas under 500 lb. pressure upon a cream of the ground mineral, repeated intermittently for several hours, in the attempt to produce a yield of carbonate of potash. Ten years earlier the same experimenter (U. S. Patent 513,001) had proposed using lime, calcium chloride and steam pressure in an autoclave to produce chloride. In 1910 Coates (U. S. Patent 947,795) proposed the addition of bacteria for the decomposition of feldspar. In 1910 Carpenter (U. S. Patent 959,841) proposed to heat the mineral intensely and cool suddenly by plunging in water, in the effort to render the feldspar amorphous, in the hope of making it more available for plant growth. None of the above processes have as yet been shown to possess industrial possibilities.

II. Wet Processes of a Chemical Nature.—Levi in 1904 (French Patent 344,246 and English Patent 13,875) and Piva in 1905 (French Patent 351,338) proposed methods for treating leucite by means of solutions of alkali or alkali earth hydrates, generally under increased pressure. The same general method for treating feldspar was claimed by Swayze in 1907 (U. S. Patent 862,676) and by Gibbs in 1909 (U. S. Patent 910,662).

Also Gibbs in 1904 (U. S. Patents 772,612 and 772,657) proposed a process of treatment with hydrofluosilicic acid, and subsequently with sulphuric acid, in order to produce potassium sulphate. In 1907 Cushman was granted U. S. Patent 851,922, a public patent which proposed the sludging of finely ground feldspar with water, the addition of a small amount of hydrofluoric acid and electrolyzing the mixture in wooden cells provided with wooden diaphragms. Under this process both potassium and aluminium hydrate passed through the cell diaphragm into the cathode compartment. This process, although perfectly practical, has not yet been made commercially possible owing to the high cost of hydrofluoric acid and the large amount of by-products formed in the process. None of the above processes have as yet been made commercial possibilities.

III. Dry Processes of a Chemical Nature, in which the Potash Salts are Volatilized.—In processes of this nature, fluxes, and in some cases fuel, for reducing purposes is ground and mixed with the feldspar, the mixture being subsequently heated until the potash salts are volatilized and collected either in the stack dust or partially collected from the gases by passing them through or over water. Swayze in 1905 (U. S. Patent 789,074) heated ground feldspar with gypsum and carbon, and proposed to collect the volatilized sulphate. Spencer and Eckel in 1909 (U. S. Patent 912,266) made a cement mixed with calcareous and silicious fluxes and green sand, a natural potash-bearing iron silicate, clinkered the mixture in a rotary cement furnace, and obtained a Portland cement, at the same time collecting the potash in the stack dust and the flue gases. In 1911 Eckell (U. S. Patent 1,011,172) proposed a somewhat similar method but heated only high enough to drive off the potash salts and not high enough to clinker the mixture. Again in 1911 Eckel (U. S. Patent 1,011,173) melted a mixture of green sand, limestone and fuel, tapped off the melted iron and slag, and recovered the potash salts from the flue gases.

Some of the processes under this heading have been tried on a large scale. No great difficulty is recorded in driving off the potash in the furnaces, but obstacles were encountered in the attempt to collect the potash from the gases. As a by-product operation in the manufacture of cements, these processes may yet come to be of some industrial importance.

IV. Dry Processes which Propose to Separate Potash as Hydroxide or Carbonate.—The old method of Bickell, proposed in 1856 (U. S. Patent 16,111), which depended upon heating a mixture of feldspar, lime, and natural phosphate rock or guano to a bright red heat, has not as yet been proved practical or successful. The process of the Soc. Romana Solfati in 1905 (French Patent 352,275), which proposes the roasting of leucite with carbonate, hydrate or nitrate of soda and lime and subsequently the passage of steam through the product to produce sodium aluminate and potassium carbonate, is possible from a chemical standpoint, but the high cost of operation has not permitted the process to come into commercial use.

*The full paper is printed in Vol. V of the *Original Communications* of the Congress, page 33.

I. Dry Process Products not Chloride.—These processes have been most experimented with, upon the mill scale of operation.

In 1900 Rhodin (U. S. Patent 641,406) and in 1901 (J. Soc. Chem. Ind., XX, 439) proposed fritting feldspar with lime and salt. According to the published results, this experimenter obtained good yields, although the process has not become a commercial success. In 1907 McKee (U. S. Patent 869,011) suggested heating a potash-bearing material containing mica with lime, salt and carbon in order to obtain a yield of potassium chloride. Cushman in 1911 (U. S. Patent 987,436) proposed mixing feldspar with lime and salts of a mineral acid capable of decomposing the silicate, giving the mixture special treatment previous to heating in a rotary furnace in order to produce the chloride. This method has been tried out on a large mill scale of operation, and the results obtained are discussed below.

II. Dry Processes Products Sulphates.—In 1911 Thompson (U. S. Patent 995,105) proposed heating to a bright red heat a mixture of feldspar, sodium acid sulphate, and sodium chloride and subsequently leaching out the potassium sulphate produced. This experimenter claims that potassium chloride is first formed, which is subsequently changed to the sulphate by the action of the acid sulphate. It is stated that this process has recently been tried on a commercial scale of operation. Sodium acid sulphate is a by-product that is reasonably cheap, although a large quantity is not available. The lack of an abundant supply of acid sulphite is perhaps the greatest drawback to the commercializing on a large scale of this process, although it is possible that it may still become of some industrial importance. Hart in 1911 (U. S. Patent 997,671) proposed to fuse feldspar with some barium compound, such as the sulphate, together with carbon, to pulverize the cool melt and subsequently to digest the product with sulphuric acid and thus produce in solution potash alum and a residue of barium sulphate and silica which is claimed to be useful as a paint pigment. Hart claims that some of the potash is volatilized during fusion. Since the fusion temperature is 1500 deg. C., it is probable that a considerable portion of the potash does volatilize, and it is possible that this difficulty may interfere with the commercial success of the process.

Wadman in 1907 (U. S. Patent 847,856) proposed heating lepidolite with potassium sulphate and leaching the product with sulphuric acid in order to obtain sulphates of lithium and potash.

The authors conclude that the most promising processes for making potash available from the natural silicates on a commercial scale of operation appear those which are conducted in the dry way, but without actual fusion of the reacting mixture.

Large-Scale Test of Cushman-Coggeshall Process.

The process which seemed to the authors most promising of successful adaptation to commercial ends is that of Cushman (U. S. Patent 987,436) coupled with the method of preparation of the materials before furnacing proposed and developed by Coggeshall (U. S. Patent 987,554).

This process has recently been given extensive trials on a large scale and interesting results have been obtained. The process consists essentially in powdering 100 parts of potash feldspar rock together with about 20 parts of lime and with or without 10 to 20 parts of rock salt. This powdered mixture is fed to the top of a moving drum about 3 ft. in diameter, in a layer about half an inch deep.

As soon as the layer is formed a strong solution of calcium chloride is applied from a series of small tubes. The $CaCl_2$ at once unites with the lime forming a so-called oxy-chloride cement and a large portion of the mixed powder is thereby at once formed into the "clumps" or aggregates lying in a bed of surplus powder. As the drum revolves the bed is removed by a scraper to a belt which delivers the mixture to a screen which separates the clumps from the residual powder. The powder is returned by a screw conveyor and elevator to the hopper above the drum again. The clumps are about the size of peas and pass from the screen directly to a rotary kiln similar to those used in burning Portland cement. The kiln is heated by a blast of air and powdered coal in the usual manner.

The clumps pass regularly down through the increasingly heated portions of the rotating kiln and roll out at the end, practically without alteration in size and shape.

A large percentage of the total potash present in the feldspar is converted into potassium chloride during the heat treatment, and very little is volatilized. The dry clumps are of a pale yellow color outside, due to the iron in the ash of the bituminous coal used, but they are snow-white inside. The clumps are finally ground, producing a pale yellow material containing as much water-soluble K_2O as hardwood ashes, although the potash is in the form of chloride, and the product also contains considerable free lime. Up to the present time no attempt has been made on a large scale to leach out the soluble potash. The ground material is being given field tests as a straight potash fertilizer containing lime.

Résumé of the Large Scale Experiments.—Potash feldspars were obtained from five different localities. Eleven carloads were used in the trials, amounting to a total of 385 tons. Each carload was ground and analyzed separately. The lowest in potash ran 6 per cent K_2O and 3 per cent Na_2O, the highest 11.3 per cent K_2O and 3.1 per cent Na_2O. The bulk of the spar ran 10 per cent potash and 2 per cent soda, and the results given in this paper were obtained on the 10 per cent spar.

The lime was a high calcium quicklime, running about 90 per cent CaO and 5.6 per cent MgO.

The salt was rock salt from New York State and ran about 98 per cent NaCl.

The calcium chloride was obtained from the Solvay Process Company. It was in the solid form and contained about 75 per cent $CaCl_2$ and 25 per cent water.

All of the above materials are available in very large quantities and at low cost. The calcium chloride is a by-product in the form of a moderately strong solution, and but a small portion is concentrated at the present time, as the chief use is for refrigeration purposes. Vast quantities are now run to waste. The solid form was used in these trials merely for convenience.

Many heats were made with mixtures of varying proportions, but the two mixtures used in the work here described were:

Feldspar,	100	Feldspar,	100
Lime,	20	Lime,	20
Salt,	10	Salt,	20

The feldspar, lime, and salt were separately crushed in gyratory crushers and rolls, and dried in a rotary drier. In continuous work the proper mixture would be made at this point by continuous weighing machines, but as a number of different mixtures were to be tried, each of the three raw materials was ground separately in Huntington mills and put into bins. This preliminary grinding of the feldspar and salt was to about 65 per cent through a 100-mesh sieve, and that of the lime about 83 per cent through the 100-mesh. The weight per cubic foot of each powder of the above fineness was then ascertained and measuring boxes were built so that the materials could be separately measured out and run together into a large mixing machine. Almost a ton was thus mixed each time. The mixture was then conveyed to a tube mill and further ground to a fineness of from 97 per cent to 99.5 per cent through a 100-mesh sieve, and then conveyed to the bin over the clumper and kiln.

The calcium chloride masses were broken up and thrown on a perforated grid in a large tank holding about 48 tons. Water was run in and the chloride dissolved most readily. The solution was run out when about 42 deg. Beaumé into two large sump tanks, and brought to a constant strength of about 42 per cent $CaCl_2$. This was then pumped up to an elevated tank

and piped from there, through a constant level tank, to the dropper tubes of the clumper placed in a row above the drum. This drum is 15.5 ft. long and 3 ft. in diameter, and is horizontal. There are fifteen valved pipes, each one feeding an adjustable pipe holding thirty-eight short dropping tubes of brass 1-16 in. internal diameter, and set 5.16 in. apart.

The finely ground mixed powder is taken from the bin by a chute, elevator and screw conveyor and distributed in a long hopper trough over the drum. It is taken from the trough by a roll device and spread evenly on the moving drum at its topmost point. The drum has a surface velocity of about 1.6 inches per second, the layer of powder advancing at this rate.

It was found that by dropping the liquid very rapidly upon the powder, the clumps could be made rapidly enough to give a full feed to the short rotary kiln when only one-third of the trough and droppers and drum is used. A clumper drum 5 feet long produces every hour almost two tons of fresh clumps and considerably over a ton and a half of burned product with the kiln used in these trials. The excess of powder passes through a screen and goes to the same elevator which lifts the original material from the bin. The amount of actual $CaCl_2$ in the fresh lime is regulated to about 20 parts to each 100 parts of feldspar in the mixture. The clumps leave the screen in rounded form and flow directly into the kiln.

The Rationale of the Chemical Engineering Operations.

The reason for the above procedure will now be explained. In the first place, calcium chloride reacts very efficiently under these conditions with the feldspar by replacing the potassium with calcium, thus forming calcium silicate and potassium chloride. Anhydrous calcium chloride is expensive to produce and it is impracticable to grind it into a mixture on a large scale on account of the rapid absorption of moisture. Even if such a dry mixture could easily be made, its use would present certain disadvantages.

When a reaction between an ore and solid fluxes is produced by heating up to the fusing temperature, then reaction takes place on the surface of the particles alone and only at the points where the ore is in actual contact with the flux particles. Finer grinding will produce a larger surface area and thus a greater number of actual contact points, leading to a larger yield. There is, however, a degree of fineness beyond which it is not wise to go, on account of the cost of extremely fine grinding.

Another factor in the problem is brought out by the following experiments. A batch of ore and the theoretical amount of solid flux were ground together to just pass a 50-mesh sieve. This powder, when subjected to a certain heat treatment, gave a reaction yield of about 35 per cent of the theoretical. The mixture was then ground to just pass a 100-mesh sieve and given the same heat treatment. A reaction yield was obtained of about 65 per cent of the theoretical.

The mixture was then ground to pass a 200-mesh sieve and again reheated as before. A smaller yield was obtained then when the material just passed the 100-mesh, although the particles were undoubtedly only half the average diameter with about four times the surface area and should therefore have had far more points of contact.

Upon weighing equal volumes of 50-mesh, 100-mesh powders, it was found that the latter contained far less material and it became apparent that the 200-mesh powder consisted for over 54 per cent of its volume simply of voids. Such finely ground powders are well known to "surge," that is, to show the tendency to flow like water through orifices in a manner resembling fountains. Material ground as fine as this is the cause of much trouble at spout slides and conveyors. Each particle of a material of this extreme fineness is undoubtedly surrounded by a film of air, the actual contact with the surfaces is lessened and friction almost eliminated. When allowed to flow into a bin, such a powder assumes an almost horizontal surface, there is practically no angle of repose. Unquestionably the lessened contact caused the low yield in the finely ground mixtures.

Some of the finer material was briquetted and the subsequent heat yield about 85 per cent of the theoretical. Briquetting is, however, expensive and usually necessitates the addition of a binding agent foreign to the reaction.

Clumping Process.

As a result of these investigations, the method was developed for aggregating fine powders by dropping a suitable liquid upon an excess of the powder in such a way as to cause a temporary bond to form, thus practically eliminating the air films or voids around the individual particles and permitting actual surface contact. Under these conditions, with the same ore and flux used in the experiments described above, the same heat treatment yielded within 3 per cent of the theoretical quantity present.

This method of aggregating finely powdered materials previous to furnacing has already been used in several different ways. For example, in an ore mixture in which the fluxing material is an alkaline carbonate, such as sodium or potassium, which forms crystalline salts containing water of crystallization, if the carbonate is used in the partially anhydrous condition and ground with the ore water alone dropped upon the mix in the manner described formed at once a crystalline carbonate which binds the particles of ore and flux into separate clumps, which are hard enough to withstand screening, while the air films are practically eliminated. Using such a mixture and process as this, a practically theoretical yield was obtained, although the flux was used only in the exact molecular proportion called for by the reaction.

By this clumping process a very intimate contact of reaction of surfaces is readily obtained at a low cost. The quantity of flux necessary to complete the reaction is greatly reduced, the duration and temperature of the heat treatment is lessened and working with rotary kilns dusting and stack losses are almost entirely eliminated. The clumps are beautifully adapted to the feed mechanism of rotary kilns, as they flow easily, do not dust and take the heat more evenly than fine powders. Now that the temperature conditions in rotary kilns can be accurately controlled, it would seem that many chemical and metallurgical reactions which are now performed by intermittent processes and with low yields could be much more economically carried out in continuous rotary kilns, taking advantage of this new method of forming aggregates previous to furnacing.

In the application of this method to the treatment of feldspathic rock, advantage was taken of the fact that a solution of calcium chloride acts upon dehydrated lime to form the oxychloride which is a strong cementing compound. It was found that the formation of calcium oxychloride gave a sufficiently strong bond to enable the aggregates to withstand the operation of screening and the burden in the kiln.

The theoretical quantity of calcium chloride flux required depends upon the total quantity of K_2O and Na_2O present in the mix, as it is evident that the soda must also be liberated in proportion to its content. The feldspar ore used ran 10 per cent K_2O and 2 per cent. Na_2O which required theoretically 15.5 parts of calcic chloride.

In all the trials some slight excess of calcium chloride has been used. The strength of the solution and the method of treatment has been such that about twenty parts of actual calcium chloride are present in the fresh clumps to every 100 parts of feldspar. The twenty parts of lime used is for the purpose of forming the aggregates, and this lime remains practically unchanged in the finished product. The presence of lime in a potash fertilizer will be found advantageous to most soils, and it is generally admitted that lime increases the manurial value of a fertilizer.

If the object was to leach out the soluble potash salts from

the product, a much smaller amount of lime could be used without interfering with the formation of hard clumps. The salt is added because it has been found to aid the heat reaction, probably mechanically as will be explained later on. The fresh clumps contain from 16 to 20 per cent of moisture, which is, of course, evaporated in the upper part of the kiln.

Treatment in the Rotary Kiln.

The rotary kiln used in these trials was one of the old bottle-shape cement kilns with a total length of slightly over 55 ft., the upper 20 ft. having a diameter of 4 ft. clear inside the firebrick lining, the lower portion widening out to nearly 6 ft. inside diameter. The pitch was ⅞ in. per foot and the most suitable speed was found to be one revolution in about 2½ minutes.

The conditions of the heat treatment are very important. The kiln used was too short to yield the best results, and after the preliminary experiments changes were made which caused the material to take about 1½ hours to pass through the length of the kiln. The temperature of the gases issuing from the upper end of the kiln were read continually with a thermo-couple pyrometer fitted with a 15-ft. fire end and temperatures were also taken from time to time at the firing platform.

A furnace wall temperature of about 1370 deg. C. is required for efficient burning of powdered bituminous coal. This is, however, much too high a temperature for potash work in a rotary kiln. This difficulty called for experimental investigations and adjustments of the heat treatment before the proper yields could be obtained. If a longer kiln had been available, there is every reason to believe that a more efficient use of the heat could have been obtained. The coal used was fairly high volatile bituminous coal. It was ground to about 94 per cent through a 100-mesh sieve and blown into the furnace under an air pressure of about 10 lb. per square inch.

During the progress of the clumps down the kiln the following reactions probably take place. At the entrance to the kiln the water begins to evaporate. As the hotter zone is approached, the temperature rises high enough to melt calcium chloride and salt. Whether the calcium chloride is free to melt is not known to the authors, as the exact composition of the oxychloride compound formed has not yet been determined. The results of their work seem to prove that the reacting chlorine is more readily evolved from the oxychloride compound than it is from calcium chloride alone. The melting of the salt, however, continues the bond of the reacting particles, causing them to thoroughly "wet" each other, and from this point on the attack on the silicate proceeds rapidly. During the heating usually from 1 to 2 per cent of Na_2O is volatilized.

When operating with no salt present, the yield of soluble potassium chloride was 47.5 per cent of that originally present in the feldspar. On adding to the mixture ten parts of salt to each 100 of spar, a test heat yielded 64 per cent, but of this 9 per cent was lost by volatilization, giving a yield of 55 per cent net in the final product. On adding twenty parts of salt to the mixture the yield grows to 69.2 per cent with no volatilization and to 75 per cent under heat conditions which caused a volatilization of 7 per cent, leaving a net yield of 68 per cent of that originally present.

In the case of clumps made from a mixture of 100 parts of feldspar containing 10 per cent K_2O and 2 per cent Na_2O, twenty parts of lime, twenty parts of salt and twenty parts of calcium chloride, the theoretical composition if no volatilization loss takes place is shown compared with the actual results obtained in the following table:

	Theory	Analysis	
Total K_2O	6.25%	5.8%	
Water soluble K_2O	.....	4.2%	Equals 6.65% KCl
Loss of K_2O	....	5%	As KCl already formed
Total Na_2O	7.69%	7.1%	5.2% made into NaCl
Water soluble Na_2O	6.37%	5.1%	Showing 1.79% vaporized as NaCl or 26% of that present

This particular product contained 11.2 per cent of free lime and total lime by analysis 15.5 per cent. There was also in this sample about 5 per cent of free unchanged calcic chloride. The amount of calcic chloride in the various runs made up to the present time have been reduced gradually to about 1 per cent., and it is felt that in the future better conditions of heat treatment will make complete use of the calcic chloride and at the same time raise the yields of soluble potash. In later runs in which only ten parts of salt were present in the mix, the theoretical and actual analysis of the product was as follows:

	Theory	Analysis	
Total K_2O	6.66%	5.62%	
Water soluble K_2O	.....	4.5%	Equals 7.12% KCl
Vaporization loss of soluble K_2O	...	1.4%	As KCl already formed
K_2O insoluble in water	.....	1.12%	
Total Na_2O	4.2%		
Water soluble Na_2O	..	3.7%	Showing 0.47% vaporized as NaCl or 11% of that present

This product contained 12.25 per cent of free lime, the total potash rendered soluble was 5.54 per cent of the product or 83.2 per cent of the total quantity present, but as 15.6 per cent had been volatilized the net yield in the product amounted to 57.6 per cent.

The material which was later made continuously according to the process described above carries 4.5 per cent of water soluble K_2O in the form of 7.12 per cent potassium chloride and in addition to this material carries only 1.12 per cent K_2O insoluble in water. It is well known that a 2 per cent citric acid solution will extract, when used according to the Wagner method soomewhat more K_2O than can be made directly water soluble. This fact is of considerable interest when the product is to be used directly as a potash fertilizer.

Conclusions—Cost of Process.

"It is believed that under better conditions of heat treatment which can be obtained with longer kilns and with a somewhat different arrangement of the combustion chamber, that slightly better yields than those reported can be obtained. It should be remembered that the kiln used in these experimental trials was originally designed for burning cement, but this type of kiln has long been superseded by improved forms. In order to get the proper heat treatment in the middle of the kiln to complete the reaction, it was necessary to have the upper part too hot. This condition will not maintain in a properly designed kiln. It is also believed that the use of oil as fuel would have allowed an easier regulation of the heat treatment but the trials so far undertaken have been made under conditions which were found available at the time.

"The subject of the costs of this process and of the product can not be gone into in detail at this time, but a few general statements may be made. The production of water-soluble potash in feldspathic rock is essentially a low-grade proposition, and the commercial success of such a process depends upon the low cost of the various operations. The manufacture of a straight potash fertilizer containing as valuable ingredients only potash and lime must be carried out on a very large scale and by the most modern methods of continuous operation. With regard to the clumping process, the trials have shown that this operation can be practically carried out as a continuous process and at an exceedingly low charge per ton of product.

"The process may be directly prepared with that of the manufacture of Portland cement. It is a little easier to grind feldspar and lime than the shales and limestones used in cement manufacture. Drying will cost no more. Chemical control of the raw mixes will not be more expensive and perhaps much less. Clumping, as has been shown, adds a very small charge to the expense of treatment. The cost of furnacing the feldspar mix will be less than similar charges in the cement industry, as the temperatures required are much lower and less coal is consumed. The product from the potash kiln is comparatively soft and pulverizes easily in hammer mills, while the charges on the cement industry for grinding

clinker is an important item. Again the softer potash product merely requires to be ground fine enough for use as a fertilizer, whereas cement clinker must be ground very fine and costs rise rapidly with increasing fineness. Repair bills in the case of feldspar treatment should be much smaller than in cement manufacture. The charge for raw materials is somewhat larger than in the case of cement but this is more than met by the smaller costs of operation.

"The potash fertilizer as now produced should be the equal in fertilizing value of the ordinary grades of hardwood ashes. The product carries practically the same content of water-soluble potash and somewhat more lime than wood ashes. There is every reason to believe that if the process becomes an industry the yields of the water soluble potash can be considerably improved. The material yielded is not a fused product, it is friable as an ash and it has the physical texture to make it a valuable aid to soil structure. The success of the product, must, of course, depend upon the results obtained under test conditions in its experimental use as a fertilizer. If results are obtained which are as good or better than those which usually attend the proper use of high grade wood ashes, it is believed that there should be no reason why this product cannot be successfully produced and introduced, especially in those parts of the country where potash feldspars, fuel and shipping facilities are available."

The Extraction of Potash from Silicate Rocks.

An abstract of a paper read before the Eighth International Congress of Applied Chemistry.

By WILLIAM H. ROSS.

The potash-bearing minerals of the United States may conveniently be divided into three classes, as follows: (1) Alunite and similar minerals; (2) the greensand marls, and (3) the igneous rocks.

(1) *Alunite* is a hydrated sulphate of aluminium and potassium. It differs from the minerals of the other two groups in that the potassium is readily available by simple ignition of the mineral to a dull red heat. (Waggaman, Circular 70, Bureau of Soils.) When occurring in sufficient quantity and purity alunite is thus a possible economic source of potash and has long served as a source of potassium alum in Italy and other countries. Its occurrence in this country is limited to comparatively small deposits in Utah, Colorado and Nevada.

(2) *Greensand,* or glauconite, is essentially a hydrated silicate of iron and potassium, but it is extremely variable in composition and never occurs pure. It is formed through the interaction of various alteration products, and organic matter is believed to play a part in its formation, which would explain its occurrence in the marl deposits of Kentucky, New Jersey, Tennessee and other states. Like the minerals of the third group it is a refractory silicate, and the potash which it contains is not readily available.

(3) The potash-bearing *igneous rocks* are among the most widely distributed minerals and occur as constituents of nearly all rocks. The principal minerals of this class from the point of view of the potash which they contain are orthoclase, or microcline, muscovite, and leucite. Millions of tons of rock containing one or more of these and related minerals with a potash content in the neighborhood of 10 per cent are to be found widely distributed all over the globe. It is for this reason that the igneous minerals, particularly the potash feldspars, are most often spoken of as a source of potash salts.

In Table 1 is given sample analyses of the most important potash-bearing minerals.

The desirability of finding some economical way of extracting potash from these minerals has long attracted the attention of various investigators and numerous patents have been issued covering processes which are claimed to solve this difficult problem.

The increasing yearly demand for potash salts in connection with artificial fertilizers has of late renewed interest in this direction, and in some cases companies have been organized for the purpose of manufacturing potash by one or other of the various processes which have been proposed, but up to the present no potash prepared in this way has been placed on the market.

Practically all methods yet proposed, in principle at least, have been covered by patents. A comparative study was therefore undertaken by the author of all processes for which patents have been allowed, with a view of finding what methods, if any, give promise of being practicable commercially.

In the present paper the results so far obtained are given.

Modifications of J. L. Smith Analytic Method.

The most convenient way of determining the alkalies in silicate rocks is the well known J. Lawrence Smith method. According to the directions usually given for this method, 0.5 gram of the ground material is mixed with an equal weight of pure ammonium chloride and 4 grams of calcium carbonate. On igniting the mixture gently at first, the ammonium chloride is volatilized and part of the calcium carbonate is converted into calcium chloride. These two compounds of calcium when heated at a temperature of about 1000 deg. C., with feldspar, or other silicate rock, bring about its decomposition, and any potash present is converted quantitatively into potassium chloride. The same result is obtained if the proper amount of calcium chloride is used instead of ammonium chloride in the first place.

Of the many patents which have been issued for extracting potash from silicate rocks, at least four may be considered modifications of the J. Lawrence Smith method, since the essential feature of each consists in heating the potash-bearing material with calcium carbonate and some metallic chloride.

I. The first of these, United States patent No. 513,001, was issued to *H. S. Blackmore* in 1894. To produce a soluble potassium salt according to this patent, orthoclase, reduced to a fine powder, is mixed with finely powdered calcium chloride in about equal proportions to the potassium silicate present. To the mixture is then added an excess of calcium oxide and a sufficient quantity of water to render the entire mass moist. This is introduced into a sealed furnace, or retort, and heated to a temperature of about 1100 deg. C., whereby the water mixed with the mass is converted into superheated steam at a high pressure, which is supposed to assist materially in the transformation of the orthoclase into soluble potassium chloride and insoluble silicates of calcium and aluminium. The heating is continued for about two hours, and, after cooling, the mass is placed in vats and lixiviated.

The part of the process as patented which requires the moist mass to be heated in a sealed furnace to a temperature of 1160 deg. C. could obviously not be carried out on a large scale, for it would not be feasible to make a furnace which would stand the pressure produced at this temperature.

II. In 1900 United States patent No. 641,406 was granted to *G. J. Rhodin* for obtaining soluble potassium salts from feldspar. In carrying out the process according to this invention, 1 part of feldspar is mixed with 1 part of lime, and 0.2 part of sodium chloride, all in a finely powdered condition. The mixture is then heated in a closed vessel of iron or other material, or else in an open-hearth or blast furnace to a bright yellow heat and maintained at that temperature for a considerable time, care being taken not to melt or fuse the mixture. The cooled mass which still remains in a powder may be applied directly as a manure, since the potash present is claimed to be rendered available by the treatment, or it may be separated from the mass by treatment with acids.

III. In 1907 United States patent No. 869,001 was issued to *Ralph H. McKee* for a process for producing potassium compounds from potash-bearing material containing mica by essentially the same treatment as that covered by Rhodin's patent for the extraction of potash from feldspar.

IV. United States patent No. 987,436 was granted to A. S. *Cushman* in 1911 for a method for obtaining potash from silicate rocks. According to this method the feldspathic rock is reduced to as fine a subdivision as possible and mixed with finely powdered quicklime in the proportion of 100 parts of the rock to 20 parts of lime. The mixture is then spread on a suitable conveyor, as belt or drum, in the form of a bed having a thickness from ⅜ to ½ in. To the surface of this bed is now applied a solution of calcium chloride in separate drops, and of such a concentration that the amount of calcium chloride added should be sufficient to supply chlorine in quantities at least molecularly equivalent to the total alkali contained in that portion of the feldspar which becomes aggregated into lumps on the addition of the solution. The aggregates, which harden quickly at ordinary temperatures, are separated from the unconverted powder by screening, and are then heated in a rotary kiln at a temperature preferably, but not necessarily, below the point at which a substantial part of the potassium chloride is sublimed.: The product is discharged continuously from the furnace in lumps and may be crushed for use directly as a fertilizer; or the potassium chloride may be extracted by means of water and recovered from the solution, or utilized therein in any preferred way.

From a comparative study which was made of these patents it does not appear that the use of sodium chloride has any advantage over calcium chloride. The latter is a by-product obtained in large quantities in the manufacture of sodium carbonate, and is somewhat more effective than the former in bringing about complete decomposition of the feldspar, but when limited amounts of the reagents are used, a somewhat larger amount of the potash is rendered soluble with the use of sodium chloride than with calcium chloride. . . .

While a considerable portion of the potash was rendered available when using approximately the proportions of the reagents stated in the patents, the total potash in the feldspar was not rendered soluble in this way at the temperature specified. Thus, when 1 part of feldspar is ignited with 1 part of calcium carbonate and 0.25 part of calcium chloride, which is 0.05 part in excess of that equivalent to the alkalies in the feldspar, only about 60 per cent of the potash in the feldspar is rendered soluble. Increasing the proportions of calcium carbonate and calcium chloride used produces a comparatively small increase in the amount of soluble potash obtained, and complete decomposition of the feldspar only takes place when 1 part is ignited, under the conditions of the experiment, with about 1 part of calcium chloride and about 2 to 3 parts of lime. When this proportion of the reagents is used, considerable variation in the temperature of ignition will give the same results, and almost the entire amount of the potash is rendered soluble at a temperature below the melting point of potassium chloride. . . .

Unless a large excess of calcium chloride is used, when ignited with feldspar and lime, no vitrification takes place on heating to a temperature up to 1050 deg. C. The ignited mass remains in the form of a powder, and consequently the soluble material present can be readily leached out without the necessity of any previous grinding of the mass. The same statements hold true when sodium chloride is used, but with a more limited variation in the proportions of the reagents which may be taken. Thus, a hardened mass is obtained when 1 part of feldspar is ignited to 1050 deg. C., and with 1 part of calcium carbonate and 0.25 part of sodium chloride, but if the proportion of calcium carbonate is doubled the mass remains in a powdered form. When calcium chloride is used, the mass does not harden on ignition, even with 1 part of calcium carbonate.

On account of its simplicity, the method of decomposing feldspar by heating with calcium carbonate and with calcium chloride (or sodium chloride) could undoubtedly be carried out on a large scale without involving any serious mechanical difficulty, and the method would thus be a practical one providing the value of the products obtained would compensate for the expense involved. Although pure feldspar may be obtained which contains upward of 15 per cent potash, the average grade of feldspar which could be mined on a large scale would undoubtedly contain less than 10 per cent. If potash be quoted at 66 cents a unit (estimated from prices quoted by the German Kali Works) then the potash in a ton of feldspar containing even 10 per cent of this constituent would be worth only $6.60 when converted into a soluble form. It is thus evident that the value of the potash alone will not compensate for its extraction by this process, or by any modifications of it for which patents have been granted; nor is it at all likely in view of the comparatively low percentage of potash in all silicate rocks that any process can be derived which will prove so simple that the value of the potash alone will pay for its extraction. It seems safe to say, therefore, that any method to be economical must produce at the same time other products of value in addition to the potassium.

Portland Cement as a By-Product.

One of the first patents on a process for converting the insoluble potash in feldspar into a soluble form was issued in 1856 to Charles Bickell (U. S. patent 16,111). The process consists in heating in a reverberatory or other suitable furnace to a light-red heat for about 2 hours 1 part feldspar, 0.5 part phosphate of lime, and 3 or 4 parts of lime, all in a finely divided state. According to the patent the potash becomes available by this treatment, and may be extracted in a caustic state by lixiviating with water, or the mass may be used directly as a manure.

At first sight this process seemed particularly attractive, for if both the potash and phosphoric acid were rendered available by this treatment, as claimed by the patent, the method might be an economical one, since when used as a fertilizer no separation of the constituents would be necessary, and the mixture would be of value for its phosphoric acid as well as its potash content.

It was found, however, that the calcium phosphate has a passive effect in this treatment of the feldspar, and that no greater decomposition was produced in this way than when it was heated with calcium carbonate alone.

Thus when 1 gram of feldspar, 0.5 gram of calcium phosphate, and 3 grams of calcium carbonate were mixed and ignited for two hours at 1000 deg. C., in a J. Lawrence Smith crucible, the amount of potash rendered soluble only amounted to about 2 per cent of the feldspar. The amount of soluble potash obtained when 1 gram of feldspar and 3 grams of calcium carbonate were ignited in the same way, likewise amounted to approximately 2 per cent, but in each case the

greater part of the residue remaining after extracting with water was decomposed when treated with dilute hydrochloric acid, the potash going into solution.

When the temperature was increased to about 1200 deg. C., the soluble potash amounted to 5 per cent of the feldspar, and the extracted residue was then found to be readily and completely decomposed by hydrochloric acid. From this solution was obtained the remaining portion of the potash which did not dissolve on digesting with water.

The crucible in which these ignitions were made was closed with a cap, and as this end of the crucible was not ignited, there was little tendency for the potash to escape, but when the ignition was made in an open platinum dish in a furnace at a temperature of about 1400 deg. C., the potash in the feldspar was found to have been completely lost by volatilization.

In carrying out this experiment the feldspar was first dried to constant weight by heating in a muffle furnace at 1000 deg. C. The calcium oxide used was likewise reduced to constant weight by igniting chemically pure calcium carbonate at a temperature of 1400 deg. C., for several hours. One gram of the feldspar and 1.68 grams of calcium oxide, equivalent to 3 grams of calcium carbonate, were then well mixed and ignited in an open dish in the furnace at 1400 deg. C., for one hour. The weight of the mixture was found to have decreased by 0.1606 gram, which is equal to 16 per cent of the feldspar. The residue was then analyzed for potassium, but only a trace was found.

The experiment was then repeated, using ten times the amount of feldspar and a corresponding amount of calcium oxide. The same care was taken as before to reduce each constituent to constant weight before mixing. After igniting for one-half hour the loss in weight of the mixture amounted to 1.3912 grams, equal to 13.9 per cent of the feldspar. On repeating the ignition for one hour a further loss in weight of 0.1630 gram took place, which was increased to 0.1768 gram on igniting for one hour longer, making a total loss of 1.5680 grams, equal to 15.7 per cent of the feldspar. Since the feldspar was shown by analysis to contain 15.9 per cent of $K_2O + Na_2O$, it would thus appear that the greater part of the alkalies in the feldspar were driven off in the form of oxides. This was confirmed by an analysis of the residue, which contained less than 0.2 per cent of total alkalies.

The hardened mass remaining after ignition strongly resembled cement clinker, and that the product obtained by igniting feldspar and lime together contains all the essential elements of a cement is well known. Using commercial feldspar and lime in the proportions of 1 to 3, a clinker approaching the composition of Portland cement is obtained, providing the feldspar does not contain an excessive amount of free silica. . . .

In order that a clay may be suited for the manufacture of cement it should have a percentage ratio of silica to alumina of from 3 to 1 to 4 to 1. The ratio of these two constituents in feldspar is 3.5 to 1. In muscovite and leucite of theoretical composition the proportion of silica to alumina is less than 3 to 1, but in commercial samples of leucite-bearing rocks the ratio is usually greater than 4 to 1.

A clinker of the same ultimate composition as that which results when feldspar and lime are heated together may also be obtained when part of the lime is replaced by sufficient calcium chloride to be equivalent to the potash and soda in the feldspar, the total calcium used remaining the same as before. In carrying out this experiment the feldspar and lime were ignited to constant weight as already described, and the calcium chloride thoroughly dried by heating in an aid bath below its melting point. Ten grams of the feldspar were well mixed with 2.0050 grams of calcium chloride and 15.7895 grams of calcium oxide, and the mixture then ignited in an open dish in the furnace at 1400 deg. C. By this treatment the alkalies are volatilized as the chlorides. On igniting for one-half hour the weight lost by the ignited mass amounted to 2.5632 grams, equal to 25.63 per cent of the feldspar. When expressed as the chlorides the percentage of alkalies in the feldspar used amounted to 25.82 per cent. It would appear, therefore, that practically the whole of the alkalies in the feldspar were volatilized during the first half hour of ignition. On continuing the ignition for one hour longer the additional decrease in weight which took place amounted to only 0.0090 gram. The residue was then analyzed for potassium and chlorine, but only a trace of each was found.

This shows that the volatilization of the potash in feldspar takes place more rapidly when part of the lime is replaced by calcium chloride than when the feldspar is ignited with lime alone, but in each case the ultimate composition of the residue obtained is the same. Any excess of calcium chloride used above that equivalent to the potassium in the feldspar is slowly decomposed at the temperature at which the ignitions were made, leaving behind the oxide of calcium.

Since the clay used in making cement contains in some cases as high as 3 or 4 per cent of potash, it might be expected that part would escape from the kiln and be collected with the flue dust, particularly in those plants where the Cottrell process for collecting dust has been installed. This has been observed by several investigators to really take place, and the potash then collected is found to be in the soluble form. By the substitution of feldspar for clay in the manufacture of cement the potash then collected would, no doubt, be greatly increased, but since the analyses of cement show the presence of alkalies, it follows that with the style of kilns now in use all the potash in feldspar could not be made available in this way. That a larger proportion of the potassium would be volatilized by substituting for a part of the lime sufficient calcium chloride to be equivalent to the potassium is evident from the experiments already referred to, and experiments are now being undertaken on a large scale to compare the practicability of this procedure with the simple ignition of feldspar and lime alone.

According to the census report for 1910 the Portland cement manufactured in the United States during the year 1909 amounted to 65,000,000 barrels, or 13,000,000 tons, valued at approximately $53,000,000. The maximum quantity of potash which it would be possible to obtain by the use of feldspar in the manufacture of this quantity of cement can be calculated if the potash content of the feldspar is known. This varies up to about 16 per cent., but if half of this, or 8 per cent, be taken as the average percentage of potash in commercial feldspar then 1 part of feldspar combined with 3 parts of lime, equal to 1.68 parts of calcium oxide, would yield 0.08 part of potash and 2.6 parts of cement. Therefore 13,000,000 tons of cement would produce 400,000 tons of potash. Again, quoting potash at 66 cents a unit, this would have a value of $26,400,000, which is three times the value of the potash salts used in this country during the year referred to and about twice the value of the imports for 1911.

Whether or not this would cover the cost of the feldspar, its transportation, and the expenses incident to the recovery of the potash can only be determined by experimentation on a large scale, but the probability that potash salts can thus be obtained in large quantities as a by-product makes this method of getting at the potash in feldspar quite promising.

Bureau of Soils, Washington, D. C.

The Salines of the United States as a Source of Potassium Salts.

A paper by **J. W. Turrentine,** of the Bureau of Soils of the Department of Agriculture of Washington, D. C., divides the salines of the United States into four groups and gives for each group the results of a determination of their contents of potassium salts.

First, Rock Salts.—Immense deposits of rock salt underlie portions of New York, northeastern Ohio, the southern peninsular of Michigan, Kansas and parts of Louisiana and Texas. In New York, Michigan, Kansas and Louisiana the deposits are entered by shafts and the salt is removed by mining methods.

Also, in these regions and in northeastern Ohio the salt is recovered by solution methods.

The analyses show that the rock-salt of these deposits so far exploited contain but very small amounts of potassium salts. As the history of these deposits is unknown, as is likewise the nature of the brine from which they were crystallized, it is impossible to say whether there is any likelihood of segregations of potassium salts underlying or overlying them. From all theoretical considerations it appears quite improbable that the known deposits of rock salt of the United States east of the

2	Railroad Valley, Nev.....	Average of 19 analyses	6.25

Rocky Mountains are associated with potassium salts other than those small amounts occluded and absorbed during the crystallization of the sodium chloride.

Second, Natural Brines (Subterranean).—They are found in the porous strata underlying numerous areas in the United States, but are utilized for the manufacture of salt on a commercial scale, principally in southern Ohio, West Virginia, and Michigan.

These natural (subterranean) brines, being less pure solutions of sodium chloride, contain more potassium than the artificial brines. But in no instances of the author's analyses do the artificial or natural brines, or the concentrates thereof, contain sufficient potassium salts to make them of commercial value as a source of potash. This is especially true in view of the fact that from none of the systems represented by the brines and mother-liquors can other than double salts of potassium be separated by simple evaporation processes.

Third, Salt Lakes.—Salt lakes and their desiccated remains are found in the arid and semi-arid regions of the western parts of the United States. The lakes are of widely varying degree of salinity, some of them being practically saturated solutions; while others have gone almost to complete dryness and are represented by brine-impregnated saline and alluvial deposits; and the nature of their saline contents varies widely, depending, among other things, on the nature of the rocks constituting their drainage area.

"The brines from the western desert basins present interesting commercial possibilities. Among the large number of brines from those regions analyzed by this bureau the two reported in

table I show largest content in potassium salts. The possibility of obtaining from them useful by-products enhance their commercial value.

Fourth, Ocean Brines.—Ocean brine constituted a source of potassium salts before the development of the Stassfurt deposits. Potassium chloride was obtained from the mother-liquors resulting in the manufacture of salt from sea-water by means of solar evaporation.

On the Pacific coast of the United States there are a number of manufacturers engaged in the preparation of salt from ocean water by means of solar evaporation or a combination of solar and artificial evaporation. The mother-liquors resulting have found no very important use, though, for the most part, they are preserved.

When the bitterns from sea-water are evaporated to dryness, it is seen from table II, a mixture of salts is obtained which contains sufficient potassium salts to make the mixture of value as a so-called "manure salt." However, the amounts in which these mother-liquors are produced are so small, that the amount of "potash" obtainable from them is inconsiderable when compared with this country's total annual consumption.

Distillation of Kelp.

A paper by **J. W. Turrentine,** of the Department of Agriculture, of Washington, D. C., gives an account of an experiment on the destructive distillation of kelp on a laboratory scale in a rotary still designed by John W. Hornsey.

The destructive distillation of kelp for the recovery of valuable distillation products and the extraction of potassium salts from the unvolatilized residue was first proposed by Stanford in England and more recently by Balch in this country. These processes, together with other proposed methods of utilizing kelps, have been discussed in Appendix Q, of Senate Document, 190, 62nd Congress, 2nd Session, which is a report on the "Fertilizer Resources of the United States."

The charge distilled in the author's experiment consisted of two samples of the Pacific kelp, *Macrocystis pyrifera.* These had been dried until their moisture content was 2.89 per cent. (= ave. of 2.67 per cent and 3.12 per cent.) The distillation continued until the evolution of distillation products had practically ceased.

Analyses of the gas samples taken at frequent intervals are given.

The liquid portion of the distillate, yet to be examined, consisted of a watery and an oily portion.

The coke resulting, representing 50.10 per cent of the weight of the original kelp, was light and porous. Its analysis showed it to contain 77.79 per cent potassium chloride. On the basis of this analysis, it is evident that from the three kilograms of kelp distilled, 751.5 grams potassium chloride were obtained.

* * *

Alunite as a Source of Potash.

A Congress paper by **W. H. Waggaman,** of the Bureau of Soils, Department of Agriculture, describes laboratory experiments on alunite as a possible source of potash.

Alunite is a double sulphate of potassium and aluminium which on heating, first gives off water and sulphur trioxide, leaving a residue consisting largely of potash alum. Upon increasing the temperature this latter compound decomposes with a further evolution of the oxides of sulphur, the final residue being chiefly potassium sulphate and alumina. In the author's experiments the oxides of sulphur began to come off at 520 deg. C. At 700 deg. C. the final decomposition of the alunite takes places.

The ignited final residue was analyzed both for potash and sulphur. It contained 15.95 per cent K_2O and 15.37 per cent SO_3, or 1.83 per cent over and above that combined as K_2SO_4.

Alunite has been used heretofore for the manufacture of potash alum (Guyot, *Comptes Rendus,* Paris, 95, 693-694, 1001-1003; Thorp, Outlines of Industrial Chemistry, p. 259,260). Either by heating to 400 deg. or 500 deg. C. and leaching out the alum thus produced, or by ignition at a higher temperature and subsequently treating the ignited residue with sulphuric acid and potassium sulphate.

The production of potassium sulphate and alum by ignition of alunite, and the collection of the evolved oxides of sulphur

by absorption in some suitable medium are covered by French patent No. 419,854.

In this patent, however, it is stated that the decomposition should not be carried to the end, but that the ignited residue should contain both potash alum and potassium sulphate, a separation of which can be afterwards made by lixiviating the residue and crystallizing the solution thus obtained. Although no reason is given why the decomposition should not be carried to an end it is probably on account of the residue, which it is claimed after lixiviation is an excellent artificial bauxite. The average price of natural bauxite in 1910, according to the figures of the U. S. Geological Survey, was $4.89 per ton.

Unless the alunite used is very pure it is doubtful if the leaching out of the potassium sulphate is economical. The experience of the author has been that an enormous volume of hot water is required to entirely free the ignite residue from soluble salts. The subsequent evaporation of this water is both tedious and expensive.

The author figures that from 1 ton (2000 lb.) of pure alunite the following products could be obtained:

Potash (K_2O), 220 lb., at 4 cents per lb	$8.80
Sulphuric Acid (52 deg. B.), 1090 lb., at $6 per ton	3.27
Alumina, 740 lb., at $4.89 per ton	1.81
	$13.88

From an economic standpoint it would seem more practical to use the ignited alunite (free from soluble aluminium compounds) directly as a fertilizer either alone or in mixed goods, since the expense of separating the soluble salts from the alumina would probably more than counterbalance the value of the alumina obtained. (The complete paper is published in the *Original Communications* of the Congress, vol. 15, p. 375.)

* * *

The Congress paper by **Edward Hart,** Easton, Pa., describing a process for the simultaneous production of potash, silica, and alumina from feldspar, was published in full in our issue of September 12, p. 634 (*Original Communications* of the Congress, vol. 2, p. 117).

* * *

A paper by **B. E. Curry** and **T. O. Smith,** of Durham, N. H., on a "Study of Soil Potassium" points out that a large amount of potassium fertilizer is not used profitably at the present time.

The effect of such salts as sodium chloride, sodium nitrate, sodium carbonate and acid phosphate is to greatly increase the solubility of the soil potassium. The reaction between these salts and the soil is chemical. Calcium carbonate, calcium sulphate, and calcium oxide have practically no effect on the solubility of soil potassium.

In many cases nitrate of soda alone produces yields as good as are obtained with a combination of nitrate of soda and potassium salts. This may be due to the effect of the nitrate of soda on the soil potassium.

From a practical point of view little profit can be expected from the use of potassium fertilizers for the production of hay. (*Original Communications* of the Congress, vol. 7, p. 51.)

* * *

A paper by **W. O. Robinson** and **W. H. Frey,** of the Department of Agriculture, on "The Use of Ground Rocks and Ground Minerals as Fertilizers," reaches the following conclusions:

Numerous field and pot experiments hitherto performed have proven that orthoclase and potash mica are not efficient potash fertilizers. At present prices the insoluble potash of orthoclase and muscovite costs more than the soluble potash of the Stassfurt salts.

Orthoclase and muscovite are present in American soils in such amounts that any economic application is, figuratively speaking, only a drop in the bucket, and surely can produce no more than proportionate yields. (*Original Communications* of Congress, vol. 7, p. 215.)

How and Why Smoke Is Injurious.

By Raymond C. Benner, Ph.D.

Dwellers in a district where soft coal is burned almost universally condemn smoke. Its injurious effects are well known in a general way. When, however, it comes to certain definite injuries done by smoke and wherein it is harmful, we find that it is not a matter of common information and, furthermore, that it has been made the subject of but comparatively few scientific studies and those not co-ordinated in the different branches.

Soot is, generally speaking, the solid matter given off during the incomplete and faulty combustion of soft coal and consists, for the greater part, of carbon, mineral matter (ash), tar and moisture, together with smaller portions of the sulphur acids (H_2SO_4, H_2SO_3, H_2S), nitrogen compounds, and occluded gases.

FIG. 1.—BUILDING IN PROCESS OF CLEANING IN BUSINESS SECTION OF PITTSBURGH. THIS BUILDING IS CLEANED ONCE A YEAR.

This composition varies between the widest limits, depending upon many factors, such as coal, air supply, temperature of furnace, etc. The following analysis of soot, made by Cohen and obtained under different conditions, shows to a certain degree, the effect of some of these factors.

FIRE PLACE.

	Original coal.	Soot 5 ft. from grate.	Soot 35 ft. from grate.
Carbon	76.80	36.45	37.22
Hydrogen	4.90	3.51	3.51
Tar	0.88	34.87	40.38
Ash	1.80	5.09	4.94

BOILER CHIMNEY.

	Original coal.	Ordinary grate fuel.	Boiler flue.	Base.	70 ft. fr m base.	Top of 110 ft. chimney.
Carbon	69.30	40.50	19.24	16.66	21.80	27.00
Hydrogen.	4.89	4.34	2.71	0.86	1.44	1.68
Tar	1.64	25.91	0.09	0.28	0.80	1.14
Ash	8.48	18.16	73.37	75.04	66.04	61.80

It will be seen by comparing the analyses given, that the percentages of tar and carbon are higher in the soot obtained by burning coal in a fire place than when it is burned under the boiler. This is due, for the most part at least, to the fact that the temperature of combustion is much higher in the boiler furnace than in the grate and other domestic installations.

The higher percentage of ash in the soot from the boiler furnace can be accounted for on the same grounds. It is a well demonstrated fact that the losses due to the solid combustible

matter in smoke are small, the economy accompanying the proper smokeless combustion of coal being obtained by the complete oxidation of the carbon monoxide, the visible gases, etc., which always accompanies the incomplete combustion of coal. Sir Roberts-Austin found, as a mean of some forty experiments, that 6 per cent of the coal is lost when the coal is burned in domestic grates, while on the other hand Scheurer-Kestener found the loss to be only 0.5 to 0.75 per cent, when burned under the boiler, where the temperature of combustion is higher.

Among the minor constituents of soot the sulphur acids are by far the most important. The amount and kind formed depend upon the factors determining the composition of the soot in general. The following analysis of soot by Cohen and Herford gives an idea of the possible distribution of the sulphur.

Passing out as SO_2, SO_3.....	71.78 per cent	60.00 per cent
Absorbed by soot	14.51 per cent	11.88 per cent
Left behind in ash	13.71 per cent	28.13 per cent

The amount of free acid in soot may be quite large, Russel, having found 4.6 — 4.3 — 7.8 per cent free H_2SO_4 while Cohen and Ruston do not report as large amounts. They find free acid to the extent of 1.62 per cent. Arsenic is also frequently present, but only in small percentages, usually less than 0.1 per cent.

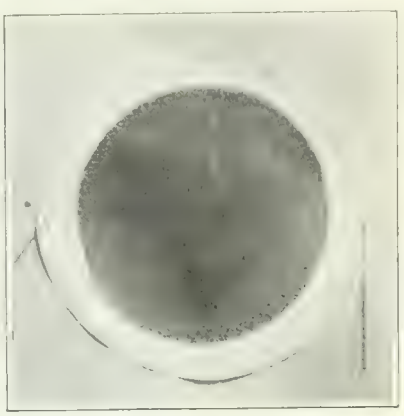

FIG. 2.—A PIECE OF FILTER PAPER THROUGH WHICH THE VOLUMES OF AIR BREATHED BY A MAN IN 24 HOURS HAS BEEN FILTERED.

The nature and composition of soot make it the worst possible kind of dirt. It is black, in fact it is the lamp black that forms the basis of black paints. Its power of absorption is great, giving it the property of occluding large quantities of injurious gases. The tar contained gives the soot the power of firmly adhering to anything with which it comes in contact, while the sulphur acids, which it contains, corrode most substances. It would be hard to imagine a more objectionable kind of dirt.

A knowledge of the chemical composition and other properties makes the injury, which soot does to vegetation, evident to one acquainted with plant structure and growth. Soot is detrimental to the healthy development of plants, inasmuch as it (1) blocks the stomata of the plants and stops, to a greater or lesser degree, the transpiration; (2) covers the leaf with an adherent black coating, which cuts down the amount of sunlight reaching the chlorophyl and because of (3) the corrosive action of the tar, acids, etc. Evergreens, more especially the conifers, seem to be much more easily affected than other plants. On evergreen plants the leaves are exposed to the action of the soot for a much longer time than those which shed their leaves at least once a year. Therefore they become covered with a thicker coating of soot. The conifers also possess sunken stomata, which act as very effective pits to catch the soot.

One might think that the excess CO_2, which is likely to accompany the soot, would make plant growth more active, but it has been found that the increased percentage of CO_2 is not great enough to be a factor. Cohen compared laurel leaves from four different localities having different amounts of soot-fall and found the relative assimilations to be 100 — 52.8 — 45.2 — 11.6 respectively and roughly proportional to the soot-fall in these places. In England, ash trees have been observed to shed the leaves 4-6 weeks earlier in the smoky districts than in districts free from smoke.

Trees automatically keep record of their yearly growth by the width of the rings. A section of a Scotch fir, noted by Cohen, shows the date of the erection of a smoke producing factory near the tree, by the decrease in the width of the rings. Vegetables, such as radishes and lettuce, planted in different parts of Leeds, have been found to be stunted in their growth nearly proportional to the soot-fall.

The effect of smoke on buildings and building materials is marked and it soon destroys the appearance of buildings which cannot be cleaned. In smoky districts it is often necessary to modify a design in some respects because of the smoke. Skylights cannot be used advantageously, as they soon become coated with the black soot. Drain pipes must be arranged so as to avoid the splashing of water on the walls. Building materials (such as glazed tile), which admit of easy cleaning, are used much more in smoky cities than elsewhere. Granite and sandstone with a silicious binder form better building materials than limestone and sandstone with calcareous binder, which is easily corroded by acid in the soot and rain. Thus the stones which are most easily worked are undesirable in smoky cities. The sulphuric acid acts on the calcium carbonate, forming calcium sulphate, which is more readily soluble than the carbonate, also causing it to swell and become porous and friable as well as more disintegrated. Dr. Smith has found mortar to contain as high as 48.16 per cent $CaSO_4$, which was formed by the action of the sulphuric acid in the air, while limestone and marble have been found to contain from 0.52 to 3.85 per cent $CaSO_4$, due to the same cause.

FIG. 3.—PILLAR IN FRONT OF CARNEGIE LIBRARY, PITTSBURGH, SHOWING DECOLORIZATION BY SOOT.

The effect on most metals of the sulphuric acid, occluded in soot, is rather marked and greater than the action of a like amount of acid in the rain-water or air. It would seem, from observations taken in Pittsburgh, that the soot containing acid is made to adhere to the metals by means of its tar content, in which place it acts as the carbon; this, together with the metal and acid, forms an electrolytic couple, making corrosion much more rapid. In case of iron and aluminium the oxide is produced, at least in part, from the sulphate, and the acid is used over and over again.

To experimentally verify these observations, duplicate sets of various metals were fastened to two boards. One set was protected from the soot in the air by means of cheese cloth, yet still exposed to the air and rain. The other set was left unprotected. The pieces of metal left unprotected from the soot show a greater amount of corrosion than those which were protected.

I wish, here, to call attention to the following figures obtained by Messrs. W. B. Worthington and A. Rattray, showing how corrosion is accelerated by the acids in the air. Quoting from Cohen. "A number of rails were placed in suitable positions by the side of the line, and weighed at intervals and the loss in weight recorded."

The rails were of the ordinary railway section, weighing 86 pounds per yard. The annual loss of weight from corrosion was as follows:

	Loss in wt. in lb. per average year.	No. of years observation.
1. In the center of the town ...	1.04	17
2. On the seacoast among sand hills	0.18	17
3. In a dry place in a smoky tunnel	1.48	13
4. In a wet place in same tunnel	1.71	8

The question of exterior and interior decoration is one affected as much by the amount of smoke in the air as by the tastes of the owners of the buildings. Interior draperies and paper are soiled much quicker in a smoky city than elsewhere. If light paper is used in papering the rooms, it must be cleaned every six months and new paper put on at least once a year to keep it looking only half as well as it would in a smoke-free city.

The effect of soot on paint is, in most cases, a matter of appearance only. The time, which it takes to spoil the paint depends, of course, on the amount of soot in the air, color of the paint, tar and acid in the soot. The number of paintings necessary in a given time depends on the above factors as well as upon the fastidiousness of the owner. In some cases the soot seems to act as a protective coating, while in others it has a corrosive action, destroying the surface gloss and rendering the surface more easily weathered.

Soot in the air of cities has a marked effect on the weather in a number of ways. By 1, cutting off the light; 2, by increasing the duration of fogs, and 3, by making the minimum temperature higher.[1]

As is well known, finely divided carbon in form of lamp black has the property of cutting off sunlight to a greater degree than most other substances. It is not surprising, then, to those of us who are acquainted with the soot clouds hanging over large cities, that the duration of sunshine has been found to be decreased 17 per cent, while if diffuse daylight is considered, the loss is even greater. Cohen finds, as an average of a large number of determinations made both in summer and winter, that fully 40 per cent of the light is cut off by the smoke-cloud and that the amount of light varies inversely as the amount of soot in the air. Dr. Russell states in his article, entitled "London Smoke and Fog," that the amount of soot in the airvaries greatly with the weather and gives the following figures to bear out his statement:

Fine weather .. .. 0.0035 gr. per 1000 cu. ft. air.
Dull weather .. .. 0.0103 gr. per 1000 cu. ft. air.
Foggy weather .. . 0.0244 gr. per 1000 cu. ft. air.

The amount of CO_2, H_2S, SO_2, together with the other gaseous products of combustion, also increase.

It may be said that each particle of moisture in a fog is formed or condenses around a solid nucleus or a dust particle. (This does not take account of ions, which are probably not of great importance in fog formation.) For this reason fogs might be thought to be of more frequent occurrence in the city than in the country. This is, however, not necessarily the case and as a matter of fact, dust particles are sufficiently numerous in the country as well as in the city for the formation of fogs. Smoke does, however, increase the blackness of a fog, making it much denser than the country fog, simply on account of the black soot particles. The fog is also apt to be of longer duration because of the oily tar in the soot, which forms a film over the outside of the drop, thus protecting it from evaporation. It is said that at least 20 per cent of the London fogs between September 1, 1902, and March 31, 1903, were artificially induced and preventable.

The amount of soot which falls on any area during a given amount of time, forms a subject of interest to the public at large as well as to the scientist. Cohen finds the air in dull weather to contain 0.0119 grams of solid matter, which he assumed to be soot, as it is always black, and these figures agree well with Russell's for dull weather. In Pittsburgh, I find that the amount of soot in the air corresponds remarkably well with the figures for the English cities.

Numerous measurements of soot-fall have been made in as many different ways by collecting rain and snow and by catching the soot in various forms of vessels.

1902 one snowfall	30 tons	Manchester . . .	100 sq. miles
	820 tons	Glasgow	per sq. mile
Snow	220 tons	Leeds	per sq. mile
Rain	259 tons	London	per sq. mile
Snow	600 tons	Indianapolis . . .	per sq. mile

Industrial center of Leeds	539 tons	per sq. mile
Suburban residence section of Leeds ...	26 tons	per sq. mile
Center of London	426 tons	per sq. mile
Sutton, Surrey, just outside the metropolitan area	58 tons	per sq. mile
Bo'ness, a small seaside village	72 tons	per sq. mile

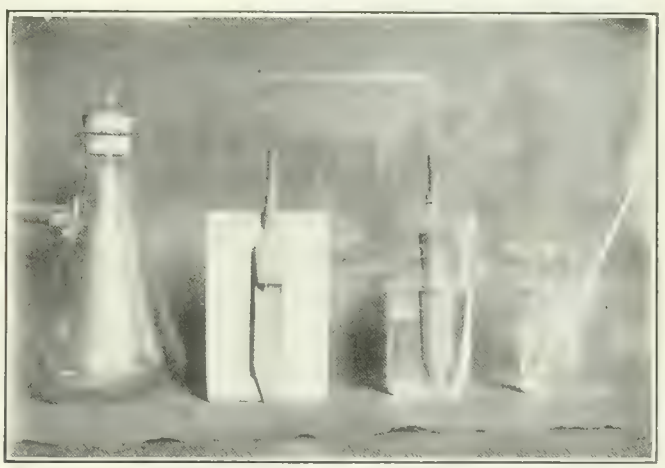
Application of the Alundum Extraction Thimble to the Determination of Copper.

By L. W. Bahney.

The photograph shows the apparatus a little less than half size consisting of a filtering flask fitted with rubber stopper through which passes a bent glass tube, and an extraction thimble fitted with rubber stopper through which passes a glass tube of ¼-inch bore. Both tubes are connected by a short piece of rubber tubing.

A section of a thimble is shown in the photograph; the tube extends to within ⅛ in. of the tapered end.

The object of using the thimble is to remove the acid from the beaker after all the copper has been precipitated. This saves time, the copper is not exposed to the acid alone, and



ALUNDUM EXTRACTION THIMBLE.

there are none of the losses attending ordinary filtration. I have formerly accomplished this by means of a piece of perforated platinum fastened in the end of a ¼-in. bore glass tube with a filter mat of asbestos, but after my supply of proper length fiber became exhausted I could not get it after purchasing fourteen lots from four different dealers. This experience makes the thimble a piece of laboratory apparatus without contingencies.

The above apparatus may be used to remove at least ⅞ of a supernatant liquid from a settled precipitate without disturbing the latter.

The application of the thimble is best shown by partly outlining the assay for copper as follows:

Dilute the acid solution of copper and other sulphates to 150 cc in a 200 cc Jena beaker, place on a hot plate, add 2 drops of concentrated HCl then place a strip of aluminium in the beaker (this may be bent or straight as desired).

Connect the apparatus shown in the photograph with a filter pump having a strong suction.

When the copper is precipitated remove the beaker from the hot plate and insert the extraction thimble alongside the strip of aluminium. The acid solution will be drawn through the porous thimble.

Wash the upper end of the aluminium strip with a jet of hot water, wash down the sides of the beaker, add about 25 cc of hot water to cover the precipitate.

As soon as all the liquid is out of the beaker, disconnect the thimble by slipping the rubber tubing from the bent glass tube of the filtering flask, wash it with a jet of hot water. If there is no adhering copper, lift the aluminium from the beaker, add 5 cc strong nitric acid to the precipitated copper and carry out the titration in the usual manner. If the copper is in a finely divided condition as a precipitate on the aluminium, it will adhere as a black coating on the thimble, but as soon as the thimble is disconnected the water inside it will ooze out through the pores and if the 5 cc of strong nitric acid is poured over it the copper will immediately dissolve, and the thimble may be washed with a jet of hot water. The filtration is more rapid when the solution is hot.

If the last of the solution in the beaker is not withdrawn as rapidly as the first, tip the beaker at an angle of 45 deg. With a pump having a strong suction this is not necessary.

The thimble attached to the flask as shown above was used in over 300 determinations.

Sheffield Scientific School,

Meeting of the (British) Iron and Steel Institute.

The fall meeting of the (British) Iron and Steel Institute was held in Leeds from Oct. 1 to 4.

The members were welcomed to Leeds by Lord Airedale and by the Deputy Lord Mayor of Leeds, the reply on behalf of the Institute being made by the president, Mr. Arthur Cooper.

The Bessemer medal for the current year was presented to Mr. J. H. Darby.

Soundness in Steel.

The first three papers presented at the meeting and discussed together had to do with different phases of the problem of the production of sound ingots.

Method of Producing Sound Ingots.

The first paper presented by Sir **Robert Hadfield** on his new "method of producing sound ingots" points out that the ingot maker is at present in a dilemma. If he makes his steel so that it will not settle, it is unsound. If he makes it sounder (using a small amount of aluminium), it pipes and so is still not satisfactory, and there is much waste. By using more aluminium he can make a steel that is quite sound, but the piping is almost as bad an evil as the unsoundness in the first case.

"The object in many steel works seems to be to try and avoid a steel which pipes or settles. This really arises from the natural desire to avoid the trouble and expense of making preparations for dealing with piping steel. The desideratum in the author's opinion is 'piping steel' which should be properly fed."

The author's new method of casting steel ingots, castings, etc., which insures soundness, freedom from piping, and absence of segregation, is illustrated in Figs. 1 and 2. It consists in heating the fluid steel in the upper part of the ingot or other mold and maintaining it in a liquid condition by the combustion, in contact therewith, or in close proximity thereto, during the cooling and shrinkage of the metal in the lower part of the mold, of solid fuel—for example, charcoal—by means of a blast of compressed air which is caused to impinge on the fuel while this is directly or indirectly supported by the metal below; and the interposition of a layer of fusible material, such as cupola slag, which has little or no injurious action on the metal, between the metal and the fuel. This slag largely prevents radiation of heat, the loss by which is much greater than ordinarily supposed to be the case.

In Fig. 2 the upper portion shows the charcoal. Then comes the layer of slag about ½ in. in thickness. Below it is the fluid steel in a 15-in. ingot-mold. The sand or other suitable top to provide the feeding head portion is inserted in the molding-box fixed on to the top of the ingot-mold itself. While the ingots can be cast as at present, that is, large end down, this particular design shows the small end of the ingot downwards. There is no doubt this is the better method, as by the small

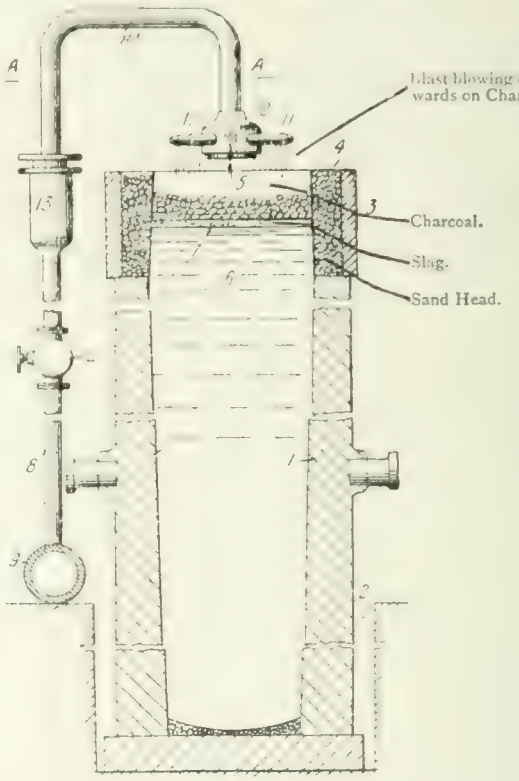

FIG. 1.—APPARATUS EMPLOYED IN PRODUCING SOUND INGOTS, SHOWING THE BLAST BLOWING DOWNWARDS ON THE CHARCOAL.

end forming the bottom portion, cooling takes place more quickly, causing the steel to congeal there and thus reduce the amount of feeding required later on from the upper portion of the mold.

"The cost of carrying out the method is trifling compared with the large saving effected by reducing loss and waste of material. Moreover, the quality of the product is improved; for example, in making rails produced from such ingots, not only is there less discard, but the material is sounder. During the last few years many thousand tons of ingots have been made by this patented process, which has been found of great advantage.

"As a specific example, it may be mentioned that ingots have been made, weighing about 5000 lb. each, in which the piping and discard do not amount to more than about 7 per cent. This small loss is not the only advantage, the chief one being that material is obtained which is quite sound and free from hidden pipes or other defects on the whole length of the ingot. The system can be applied equally well to either smaller or larger ingots, for all kinds of purposes, and for ordinary or special steels.

"It is estimated that on a large output the saving by this method is from about 8 s. to 12 s. ($2 to $3) per ton. Thus, on a large tonnage of hundreds of thousands of tons annually there would be a very considerable saving each year, as well as obtaining sound ingots free from blowholes, piping, and segregation.

"In this experiment even the segregation usually noticed was almost entirely absent, only a few inches below the feeding

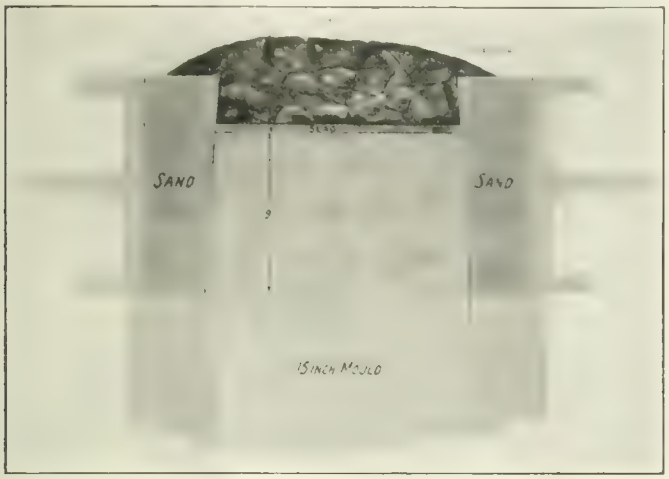

FIG. 2.—METHOD OF MAKING THE INGOTS.

head placed on the top of the ingot. At about 4 in. below the surface of the sinking head the percentages of sulphur and phosphorus were practically the same as in the original steel, namely, about 0.03 per cent each."

The paper gives a great many details of the results obtained with the process in commercial practice.

Revealing Segregation in Steel Ingots.

A second paper by Sir **Robert Hadfield** dealt with "a new method of revealing segregation in steel ingots."

At a certain stage of the cooling-down process of molten steel the complex phenomenon of liquidation is met with and causes much difficulty. While sulphur and phosphorus give the most trouble, these remarks also apply to the element carbon and the metal manganese alloyed with iron, and to a less extent as regards nickel and chromium. This segregation of the elements referred to gives a brittle, impure, and weak steel, which in the finished article may prove not merely objectionable but dangerous. There is no proof that segregation occurs in fluid steel itself, that is, all the elements are then well fused and not segregated; the difficulty begins as soon as the mass commences to cool down; in other words, segregation appears to be a function of the lowering of the temperature. The difficulty only arises in cooling down, and in that portion of the ingot or casting where the ferro-static pressure is lowest.

The author's research as to a method for revealing the way how segregation arises "commenced in this manner. It was reasoned that possibly some addition, preferably metallic, could be made to steel while in its molten or partly fluid condition which would give the desired effect. Thus upon breaking up the ingot when cold, if it would show the presence of the added metal in some clear and definite manner, such as by difference in color, useful information would be obtained. The author, therefore, after a considerable number of experiments with various metals, selected copper, which, by its slightly higher specific gravity as compared with iron, would have a tendency to fall or drop down the central portion of the ingot being experimented upon; moreover, by its distinctive color at the parts where it is alloyed with the iron its presence would be apparent."

The results of various experiments made by the author with this method are described and shown in elaborate diagrams. The first experiment described was made with a small ingot of steel (with an ingot mold of cast iron and an ingot head of sand to keep the metal in the lead fluid for a longer time); soon after the ingot was cast a little molten copper was poured into the head. It was found that it penetrated into those portions of the ingot where piping usually takes place, and thus indicated the exact location where what may be termed intercrystalline unsoundness or segregation is developed. It may be mentioned that this particular type of inter-crystalline unsoundness is not usually seen or detected in the fracture of an ordinary ingot when cold; it is only revealed by a polished section after etching. The cuprous areas in these small ingots probably represent these segregation areas.

One of the general results clearly shown by the author's experiments is that "the interior of an ingot, even of small size—and it will be, therefore, more so in a large ingot—remains hotter for a much longer period than has been thought to be the case. It can, therefore, be more readily understood why segregation proves so harmful, for, owing to this longer time of cooling and the reduction in the ferro-static pressure, naturally much greater opportunity occurs for the liquation of such harmful elements, sulphur and phosphorus. The more quickly the steel sets, the less opportunity is therefore given for this segregation. The fact has long been known in a practical way, but the reason for it has not been so apparent. The results of the present experiments seem to clearly indicate why quick cooling is advantageous."

Improving Soundness of Steel by Thermit.

A paper by Dr. **Hans Goldschmidt**, of Essen-Ruhr, Germany, describes "a new method for the improvement of the soundness of steel ingots by the aid of thermit." Dr. Goldschmidt explains the loss of homogeneity of molten steel in the course of solidifying as follows:

Steel, made by a fusion process, must be regarded as an alloy of iron with several elements, more particularly carbon, manganese and silicon; phosphorus, sulphur and copper being also present as impurities. The purer the iron the higher its melting point. The other constituents of the alloy, especially carbon, and also phosphorus and sulphur, have the effect of lowering the melting point. In the production of steel, therefore, the purest constituents, that is, those which have the highest melting point, are the first to solidify and settle at the bottom and sides of the ingot mold. At the center and head of the ingot, on the other hand, where the metal remains longest fluid, are gathered the more readily fusible impure elements which have separated out during cooling. The principal elements which accumulate near the top in this way are sulphur and phosphorus, etc., which exercise so injurious an influence on the mechanical properties of the material.

The serviceableness of an ingot is not only reduced by the process of segregation, but by a whole series of other defects arising during cooling and freezing.

For instance, during the transition from the liquid to the solid condition the volume of the ingot undergoes a change due to shrinkage. As solidification progresses from the sides and bottom inwards and upwards, the neighboring layer of liquid and semi-liquid material are attracted owing to the gradual diminution of the volume until finally, in the center of the ingot and towards the end, a large hollow space, known as the pipe, is formed, which is the distinctive and objectionable defect of almost all steel ingots. There is further the evolution of gases and the formation of blowholes.

The question of the prevention of piping in ingots is one that has always occupied the attention of metallurgists, and, among other remedies, the use of thermit was long ago recommended. The method of its application was to break open the crust which formed at the top of the metal in the mold and to plunge a cartridge filled with thermit into the pipe in order to remelt the surrounding parts. As soon as this remelting was effected, the hole was filled by pouring in fresh liquid steel from the ladle. The process as thus carried out was, therefore, a purely thermal one.

Unfortunately the method did not yield the desired results in spite of the numerous trials made at a great many steel works. In fact, it was only in exceptional cases that success was obtained, so that it was no wonder that this so-called anti-piping thermit process was soon discredited and forgotten.

Latterly, however, a new and very successful improvement of that old process has been made, which has proved very efficacious, especially in the treatment of non-siliconized steel, that is, steel to which no silicon addition has been made either in the furnace or in the ladle. At first sight it might be thought that the method had been altered only in one small detail, for the apparatus, consisting of a sheet metal cartridge filled with thermit, has been retained. It differs totally, however, in the mode of application and the result achieved.

Whereas formerly the thermit cartridge was used solely for the purpose of melting the upper portion of the ingot containing the pipe, the lower end having already solidified, the cartridge, according to the new method, is quickly plunged right to the bottom of the ingot before solidification has begun to set in, that is, before any of the defects referred to have had time to take effect. The reaction immediately causes an energetic ebullition of the liquid contents of the ingot mold. The most noticeable feature is the sinking down of the liquid metal in the mold by more than a hand's breadth as soon as the reaction is complete, and the density of the material is increased by an amount corresponding to this reduction of volume. Further metal is then poured in from the ladle until the level of the ingot is restored, and the ingot, if of non-siliconized steel, is then covered with an iron plate in the usual way.

The violent frothing up, due to the reaction of thermit, has other good effects, for the segregation already accumulating in the center is driven upwards and further segregation is prevented.

The new method has proved particularly effective for the treatment of ingots intended for **rolling into plates**, and the advantages here are very apparent. In this connection the new process was first tried at a steel works combined with a plate rolling mill, namely, the German firm of Schulz-Knaudt, A. G., and it was due to the enterprise of the steel works manager, Dr. Canaris, assisted by Mr. Biewent, engineer of Messrs. Th. Goldschmidt, A. G., of Essen, that the process was first put into practical operation.

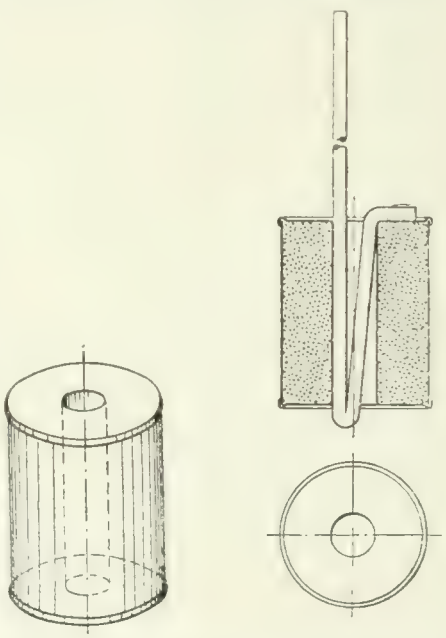
Referring now to the results obtained with plates rolled from slabs treated with thermit in this manner during the trial of the thermit process at those steel works more than 4000 ingots, varying from 1 to 8 tons in weight, were treated as described, and exact records were kept of the working results. (From Nov. 1, 1911, till July 31 of this year 17,891 ingots were treated in the same steel works. The ingots varied from 1 to 11 tons and emanated from 1436 different heats.) It was found that the number of plates rejected, owing to the faultiness of the ingot, amounted only to 0.3 per cent of the total weight of the ingots, whereas in many works the percentage of rejection amounts, as is well known, to 15 per cent or more. That figure of 0.3 per cent could have been still further reduced if the defects due to rolling alone had been also taken into account.

In view of the fact that the quality of the ingots was improved in every respect, and that a much greater regularity in working was ensured, it was soon found possible, keeping the plates the same weight as before, to reduce the weight of all the ingots by 5 per cent, that is, to make them 5 per cent less weight than is required in general practice. The principal advantage is that due to economy in rejections, but whereas this saving cannot very easily be calculated in exact figures, the advantage due to the 5 per cent reduction in the weight of the ingot can be accurately computed. Assuming that the rough finished plates are worth £6 a ton and that scrap costs £3 a ton, the difference in value of the raw material and the finished product is £3 per ton, or 60 s., that is to say, the 5 per cent reduction in weight represents a saving of $5 \times 60 \div 100 = 3$s. Since the cost of the thermit process, under the least favorable conditions, that is, if only small ingots are cast, does not exceed 1s 6d per ton of ingot, a saving of at least 1s 6d per ton of plates rolled results. In the case of large ingots the economy is considerably greater for the reason that the cost of the thermit treatment is then reduced to one-half or even less. The proportion of wages and consumption of red iron is the same for a large as for a small ingot, while the quantity of thermit used is relatively smaller per unit of metal.

Further advantages are that the quality of the plates produced is much improved, and, in particular, the strength in different parts of the plate is much more uniform, this being due to the prevention of segregation. Added to this there is also the capability of increasing the output without injuring the plant, and the quantity of waste is much reduced. The working of the rolling mill proceeds with greater regularity owing to the reduction of the number of wasters to a minimum. Therefore, no interruptions need occur in the execution of orders. Dr. Canaris pronounces the process to be an ideal means for the improvement of the quality of the ingots.

Tables are given in the paper showing analyses and tensile tests of thermit-treated plates, further comparisons of the mechanical properties of thermit-treated plates with untreated plates.

Another important advantage of the process is that for carrying it out no special apparatus is necessary, and no cost is incurred for the instalment of such apparatus. All that is required is the sheet-iron box with thermit of the proper capacity and an iron rod, by the aid of which the box is thrust down into the molten metal.



FIGS. 3 AND 4.—SHOWING THERMIT CARTRIDGE AND ROD FOR PUSHING TO THE BOTTOM OF THE INGOT.

The exact method of carrying out the process on ingots of non-siliconized material is as follows: the filling of the ingot mold is effected in the usual way, either by direct pouring into each mold from above or filling a number of molds simultaneously by bottom-pouring. After filling, the molds are left undisturbed until the crust, which starts from the sides of the mold, has spread some little way inwards. This crust gives an indication of the progress of cooling, and hence of the right moment at which to introduce the thermit cartridges. The width which the crust should be allowed to attain depends, of course, upon the size of the ingot, and is a matter that can only be judged by experience.

The thermit cartridge (Fig. 3) is preheated, and by means of the rod shown in Fig. 4 is thrust vertically down to the bottom of the ingot mold and is held there till the reaction is complete, the rod being then withdrawn. A scrap-iron rod will serve the purpose and should be about ½ in. in diameter, or somewhat stouter for the larger boxes. To economize material the bar can be made so that either end can be used.

If the operation is performed at the right moment the surface of the ingot sinks down at once by several inches or more directly the boiling ceases. More metal is then poured in at

the top until the surface is again restored to the original level, where the crust first began to form, and an iron plate is then lightly placed on the metal in the usual way and then covered up with sand.

The process is actually nothing less than a stirring up process, that is to say, a purely mechanical and not a thermal one. Since the weight of thermit required for a 1-ton ingot is only a little over 1 lb., the rise of temperature is practically nil.

The certainty of being able to produce sound ingots with a very small proportion of discard makes it probable that in future ingots of large size only will be cast, from which small-size plates will be rolled. The waste due to trimming and cutting up will be inconsiderable. Up till now it has been inadvisable to make large ingots on account of the large percentage of discard and the resulting disproportionate waste of material. The increase of density and the improvement in quality of the steel are also to be reckoned as economies, and it is by no means unlikely that the thermit process may lead to modifications in rolling-mill practice generally.

Improvements in Yield.

A Modification of the Pig Iron, Scrap, and Ore Process.

Mr. F. W. Paul, of Glasgow, presented a paper on the "manufacture of open-hearth steel with reference to improvement in yield." The author discussed the reasons why in the development of the open-hearth steel process the hope for an increase of yield with an increase of furnace capacity and weight of charges had not been realized. He also gave some details of a new way of conducting the pig iron, scrap, and ore process which in a few trials in practice in 80-ton furnaces had resulted in an increase of yield by 5 to 7 per cent.

One of the direct causes of actual decrease of yield with increase of furnace capacity is, in the author's opinion, the reduced ratio of bath area to weight of charge. While in 1880 for a 10-ton charge the bath area was 140 sq. ft., it is in the present year for an 80-ton charge only 490 sq. ft., so that the area ratio has been reduced from 14 to 6.1 sq. ft. per ton.

The author's proposed new method of charging and silicon elimination in the pig iron, scrap, and ore process is as follows:

Charging.—Instead of the pig iron being charged in one continuous operation, only a small fraction is taken, about 5 to 10 per cent, and brought to a molten state, and thereafter the subsequent additions of pig iron are charged into this initial bath of molten metal, which is maintained in liquid form substantially during the entire period of charging.

After the pig iron is all charged, and the silicon sufficiently removed to permit of superheating the metal without loss, or after the metal has been brought to the boil, the steel scrap is charged in such increments and at such rate as is commensurate with the heating capabilities of the furnace maintaining the bath in liquid form.

As regards the use of molten pig iron in basic or acid furnaces, this method of dealing with fractions of the charge *pari passu*, with additions of iron oxide, permits of the elimination of silicon at low temperature and so avoids the fluxing of the banks and thus affords, in the basic especially, means of working with low-sulphur pig iron and greater latitude as regards contents of silicon.

Melting.—The heat of the flame is in direct contact with each successive addition of pig iron and scrap floating on the surface, consequently the gas and air can be maintained at their maximum and the temperature of the furnace and metal regulated by the rate at which cold material is fed into the furnace.

The pig iron and scrap floating in a molten bath of metal with a protective coating of slag are protected from the oxidizing atmosphere of the furnace. Less waste ensues and the yield is increased.

Elimination of Silicon.—Another important feature of this method is the practical means of arranging the most suitable conditions for removal of silicon and obtaining its equivalent reduction of iron from iron ore without diminishing the number of charges per week.

During the additions of pig iron as described above under "Charging," oxide of iron is added in sufficient quantity to eliminate the silicon. By this means the melting stage and the silicon elimination stage are merged into one. The elimination of silicon is carried on concurrently with melting. That is, for a period of six hours or more with the metal at low temperature, so that the scouring action on the banks is considerably diminished. The silicon should be eliminated previous to charging the steel scrap.

An Analysis of Steel-Works Yields from Practice.

A paper on "steel-works yields" by Messrs. **Percy Longmuir** and **W. H. Robinson,** of Sheffield, was then presented by the former.

Studies of production have as an ultimate object increased efficiency. In some cases efficiency is judged by quantities, in others by quality of product. Irrespective of the point of view, before any alterations in method are tried, cut-and-dried data as to existing practice should be obtained. With this end in view a very close study has been made by the authors of the conditions of production in a steel works engaged on products of high quality and wide variety.

Metallic Yield.—The yield of a process is here taken as including all metallic products. Scrap—that is, runners and defectives—are differentiated later. The yield figure obtained is calculated from the metallic portion of the charge; thus, in the case of the open-hearth steel, ore and scale are not counted as portions of the metallic charge. The data from this source are given in a table of the Appendix of the paper, which is not reproduced here, and the figures there shown when averaged give the following values:—

Weekly Yield and Loss Per Cent. as Averaged from the Year's Working.

Type of Steel	Yield. Per Cent.	Loss. Per Cent.
Bessemer	88.81	11.19
Open-hearth basic	95.35	4.65
Open-hearth acid	96.24	3.76
Crucible	98.81	1.19

Higher yields than these have been published. However, it should be noted that the authors' records do not represent selected runs, but the whole of a year's working, and they, therefore, give all varieties of condition as regards plant and its operation.

An analysis of the metallic product includes defective steel and scrap produced in the steel-making operations. The year's working in this respect is summarized in another table, not reproduced here.

This table when averaged as in the previous case, gives the following weekly values:

Weekly Defective and Scrap Per Cent. as Averaged from the Year's Working.

Type of Steel.	Defective. Per Cent.	Scrap. Per Cent.
Bessemer	0.26	4.06
Open-hearth basic	0.24	1.65
Open-hearth acid	0.14	2.37
Crucible	0.52	14.93

Defective and scrap are self-evident terms. Certain fluctuations are shown in the weekly returns, and it should be noted that the volume of scrap is very largely determined by the type of ingot and the method of casting, conditions subject to variation according to the type of work in hand. All crucible ingots are topped down to approximately one inch below the bottom of the pipe before passing forward to the mills. The low percentage of scrap in this case is due to the use of white-hot clay feeding heads.

After actual steel-making, the first selective process is that of reduction from ingot into billet, bloom, or rail, and it is here that the effects of cropping off piped portions, short lengths,

etc., are felt. The weekly results are given in another table, not reproduced here. The range of steels varied from 0.10 per cent to 1.45 per cent with a general average of about, 0.80 per cent. carbon. The data included in that table when averaged is shown to yield:—

Rail and Billet Mill Results. Weekly Average, Year Ending December, 1911.

Type of Steel.	Good. Per Cent.	Defective Rolling. Per Cent.	Scrap. Per Cent.	Loss. Per Cent.
Bessemer	78.03	0.10	18.01	3.20
Open-hearth basic	79.63	0.03	17.28	3.06
Open-hearth acid	77.20	0.08	19.84	2.88

The bar mill values are given in another table, and these give a weekly average as follows:—

Bar Mill Results.

Type of Steel.	Good. Per Cent.	Defective Rolling. Per Cent.	Scrap. Per Cent.	Loss. Per Cent.
Bessemer	94.28	....	1.97	3.75
Open-hearth basic	95.05	0.01	0.89	4.05
Open-hearth acid	93.55	0.01	2.62	3.82
Crucible	93.68	0.08	2.71	3.53

The bar mill product is of a very varied character, and includes a large proportion of hot rolled strip steel. The greater stringency of conditions in a rod mill is exemplified in another table. The substance of this table is as follows:—

Rod Mill Results.

Type of Steel.	Good. Per Cent.	Defective Rolling. Per Cent.	Scrap. Per Cent.	Loss. Per Cent.
Bessemer	90.25	2.21	3.38	4.16
Open-hearth basic	89.98	2.95	2.84	4.23
Open-hearth acid	90.68	2.74	2.66	3.92
Crucible	92.53	0.79	2.96	3.72

Turning to an entirely different type of product, namely, tires and axles, the conditions differ as regards scrap in that greater allowances have to be made. A hole has to be punched through the tire block, and a certain latitude has to be allowed in the case of forging axle blooms. Tire results are given in a further table, and when summarized yield the following weekly averages:—

Tire Results.

Type of Steel.	Good. Per Cent.	Defective Rolling. Per Cent.	Scrap. Per Cent.	Loss. Per Cent.
Bessemer	81.71	0.01	14.82	3.46
Open-hearth acid	84.42	0.18	11.94	3.46

For the axle values the weekly average is as follows:—

Axle-forging Results.

Type of Steel.	Good. Per Cent.	Defective Forging. Per Cent.	Scrap. Per Cent.	Loss. Per Cent.
Bessemer	86.23	....	10.14	3.63
Open-hearth acid	85.78	0.19	10.68	3.35

"The labor of collecting the data here presented has not been light, and the authors have to thank Mr. H. Greenwood for his accurate work in this direction. The authors' thanks are due to Mr. F. Scott Smith, general manager of Messrs. S. Fox & Co., Ltd., Sheffield, for his sympathetic encouragement and for his ready permission to publish the data obtained.

"Finally, the collection of data of this kind forms a very considerable help to the management in the way of production and costing. Before any changes are made, it is most essential that the real work of existing plant be known. Real work can only be found by long observation, and in this direction selected runs or selected periods are useless and misleading."

The last two papers were discussed together.

An account of the discussions as well as of the further proceedings of the meeting will be given in the monthly letter of our London correspondence in our next issue.

Some further abstracts of papers presented at the meeting are here added, prepared from advance copies, which were sent to us by the Secretary of the Institute.

Iron and Nitrogen.

A paper by **J. H. Andrew** of the University Manchester gives an account of experiments on the effect of nitrogen gas on the critical ranges of the iron-carbon alloys. The method of investigation consisted in melting the metal under a moderately high pressure of nitrogen gas and then cooling the product as quickly as possible in order to retain the maximum amount of gas. For these experiments a high-pressure electric furnace was used. The chief conclusions of the author are as follows:

Iron and iron-carbon alloys absorb small amounts of nitrogen when melted under a high pressure of the gas.

The absorption of 0.3 per cent of nitrogen entirely suppresses the critical changes occurring in pure iron, and prolonged heating in vacuo is required in order to denitrogenize the metal.

The absorption of 0.25 per cent of nitrogen by a 0.6 per cent carbon steel lowers the Ar1 point to a marked degree. Such a nitrogenized steel can only be brought back to the normal state of a pure steel by several weeks' heating in vacuo.

The author considers that the critical changes occurring in iron and steel are due to the coalescence of like molecules, and that this coalescence is due to the contraction of the metal during cooling, bringing the molecules sufficiently near together for the force due to the molecular attraction of like molecules to exert itself, and overcome the influence of the intervening molecules.

The absorption of nitrogen, followed by the formation of iron nitride, prevents the iron molecules and the iron carbide molecules from coalescing with molecules of their kind by keeping them apart. This will necessitate greater contraction of the metal, and therefore a lower temperature, before the like molecules are brought sufficiently near together for the force due to molecular attraction to effect a change.

The effect of nitrogen upon the mechanical properties is made evident by consideration of its influence upon the critical change.

Hydrogen has no influence upon the critical changes when introduced into the liquid metal under pressure.

The Magnetic Properties of Manganese and Nickel Steels.

A paper by Dr. **S. Hilpert**, of Charlottenburg, Germany, and Dr. **W. Mathesius**, of Worcester, Mass., gives the results of an investigation in which the magnetic properties (intensity of magnetization and coercive force) of previously heat-treated steels were measured at ordinary temperatures. Three of the steels investigated contained from 12 to 27 per cent of nickel, 0.5 manganese and 0.12 to 0.21 per cent of carbon. Four of the steels contained no nickel, from 4.6 to 20.8 per cent manganese and from 0.27 to 2.18 per cent carbon. Diagrams are plotted for the majority of the steels, which give a clear indication of the dependence of the magnetic properties upon the previous heat treatment.

In all the steels the magnetizability after quenching from 1200° C. was greatly increased as compared with that of the same material after similar treatment at lower temperatures and also after slow cooling. By means of systematic thermal treatment in combination with magnetic measurements, it is shown that at high temperatures (above 1050° C.) substances are formed which at ordinary temperatures are strongly magnetic, but in spite of quenching cannot be obtained in a pure state. The assumption that gamma-iron must always be non-magnetic cannot be maintained. In general the dependence of the magnetic properties upon the previous heat treatment is too complex to permit of explanation by the usual theory of allotropy.

All the steels, with the exception of the nickel steel with 31 per cent of nickel, showed both in the quenched and in the slowly-cooled specimens an increase in the magnetizability when annealed at temperatures between 400° and 450° C. This is not, in any case, an aging phenomenon, but is the result of a

new state which is obtained only by a heating process. In general, the fact whether the heat treatment has been carried out under a rising or a falling temperature has a decisive influence upon the magnetic properties.

The metallographic investigation in relation to the magnetic properties showed that there was no distinctive structure which was characteristic for magnetic and non-magnetic steels.

Gases Evolved from Steel.

A paper by **G. Wesley Austin** gives the results of experiments carried out in the University of Birmingham "on the gases evolved on heating steel to its melting point in a vacuum." The samples of the steel under tests were used in form of rods between copper terminals and melted electrically by strong currents (1,000 to 20,000 emperes). The rod was contained in an air-tight furnace in form of a weldless steel tube from which the air and gases were pumped out.

In conducting an experiment the heating was carried out in three stages, each of half an hour's duration. The current was first adjusted to raise the bar to a temperature not exceeding 900° C. The temperature was next increased to about 1100° C., and finally, in the third stage, the bar was fused. The gases evolved during the several stages were separately collected.

Samples of the following five materials were treated: Cast iron of soft grey quality, cupola melted; Sheffield crucible steel; medium open-hearth steel; mild open-hearth steel; mild Bessemer steel.

In the case of cast iron and crucible steel the different extracts of gases did not materially differ in composition; for example, a cast iron specimen at a red heat evolved gases containing 24.0 per cent carbon monoxide, while immediately prior to fusion the gases contained 22.5 per cent, the difference being relatively slight. The percentage of carbon monoxide was rather lower in the gas obtained at lower temperatures, than at higher heats from medium carbon steel. Thus one specimen yielded a first extract containing 34.7 per cent carbon monoxide and the last 42.7 per cent.

The first extracts from the mild open-hearth steel were undoubtedly richer in hydrogen, one specimen evolving at first a gas of the composition:

	Per Cent
Carbon dioxide	7.7
Carbon monoxide	18.4
Hydrogen	50.1
Nitrogen	14.8

whereas the gases evolved from two specimens during the last stage in the heating yielded

	I	II
	Per Cent	Per Cent
Carbon dioxide	1.4	1.5
Carbon monoxide	65.7	59.0
Hydrogen, nitrogen, etc.	32.9	39.5

In consideration of the somewhat uneven heating and melting of the bar, definite conclusions cannot be drawn regarding the precise amount or composition of the gas evolved during a certain temperature interval. It will be observed however, that:—

1. The volume of gas evolved from cast iron is relatively much smaller than from steel; moreover, the percentage of carbon monoxide is considerably lower.

2. The higher the carbon content of the steel the larger the amount of evolved gas.

Problems of Wire Drawing.

A paper by **Percy Longmuir**, of Sheffield, discusses some "aspects of wire drawing."

The physical condition of the rod is discussed at some length. If cold-working is to be effective, the rod must be uniform throughout its length. With the long lengths of today perfect uniformity in the rod "as rolled" is impossible, and of necessity the finishing temperature of the back end differs materially from that of the front end. There is, therefore, a corresponding difference in the condition of the rod, and, generally speaking, it will be found gradually to increase in hardness from the beginning to the end of the coil. This difference between the ends may be comparatively light, but unless the rod is initially equalized throughout its effect will be felt in the later stages of drawing.

Results of tests are given in which special efforts were made to insure uniform conditions in rolling. The length of the rod was 1154 feet. The maximum stress in this case was at the beginning of the coil 47 tons per square inch and at the end of the coil 50 tons per square inch.

The difference between the back and front end is in this favorable case only 3 tons per square inch on the maximum stress. Slight as this difference may appear to be, it would, in the absence of a normalizing process, have a very material effect on the "flow" of the wire during drawing.

"Industrial 'flow' demands equality of section, therefore the reduction in area effected by drawing through a plate must be uniformly consistent throughout the length of the wire. The general tendency is to put cold work on a hot rolled rod before any normalizing has been effected, and in these cases the effect of cold working is such as to develop a habit which persists through later annealing stages. This habit may take the form of 'non-sizing'—that is, pulling out the hole, or acute local brittleness. In either case the wire-drawer usually blames the steel, and so far as the Yorkshire wire-drawing districts are concerned, the usual phrase is: 'The composition has been altered.'

"Many cases have been investigated, and in not one instance has composition been found to be at fault. In all cases the steel, considered as steel only, has been found to be correct, but its manipulation has been wrong. One of the first studies in manipulation is that of obtaining physical uniformity throughout the length of the wire, and it is here that the least work has been done.

"If the rod as hot rolled is not in a state of equilibrium, then cold work intensifies, and to some extent fixes, its condition, and later heat treatment does not necessarily remove a 'fixed habit.' The first care of the wire-drawer should, therefore, be that of effective normalization, and this may be obtained by patenting or annealing. In either case the process must have some relation to the thermal transformations of the steel in question.

"A study of current wire-drawing practice reveals the fact that generally annealing operations have no relation to thermal transformations. Temperatures are rarely taken, and the only guide is empirical judgment. Over a variety of practice the range in temperature may be estimated to vary from 550° to 700° C. Both temperature and time decrease with the reduction of the wire in size. This would indicate that wire-drawers have to some extent intuitively recognized that only the effect of the cold working has to be removed, and therefore, Goerens' 'low'-temperature annealing has long been recognized in practice.

"The effectiveness of this annealing is open to question, and not only is the 'flow' less the lower the temperature, but further, the resulting hardness is greater. Advantage can be taken of this fact when working to a definite hardness value in either cold rolled strip or drawn wire. By suitable adjustment of annealing temperatures to cold work a given hardness can be obtained, to a certain extent, irrespective of the composition of the steel. This emphasizes the fact that if annealing temperatures are to be seriously studied, then a sharp line must be drawn between the first and the latter annealings. The first annealing should relate solely to the condition of the hot-rolled rod, while later annealings have a relation to the stresses developed by cold working."

In the concluding part of the paper the author gives extensive tables showing the tensile values obtained from successive

stages of cold work without any special heat treatment after the initial one before the cold work begins. One of the tables illustrates very well the fact that cold work can be so adjusted as to give, within limits, hardness irrespective of composition.

Other papers presented at the meeting were the following on new type:

A New Type and Method of Construction of Large Gas Engines (vertical duplex type), by **Alan E. L. Chorlton,** of Manchester.

Does Commercial Hyper-Eutectic White Iron Free from Manganese Exist? by **Prof. Henry M. Howe,** of Columbia University, New York City.

The Iron Ore Resources of Chili, with a note on the Corral Iron and Steel Works, with its wood-fired blast furnaces, by **Charles Vattier,** delegate of the Chilian Government.

The Growth of Cast Irons after Repeated Heatings (Parts V and VI) by **Prof. H. F. Rugan,** of Tulane University of Louisiana, New Orleans, La.

The Solubility or Diffusion of Hardenite in Ferrite, by **Prof. J. O. Arnold** and **C. Chapell,** of the University of Sheffield.

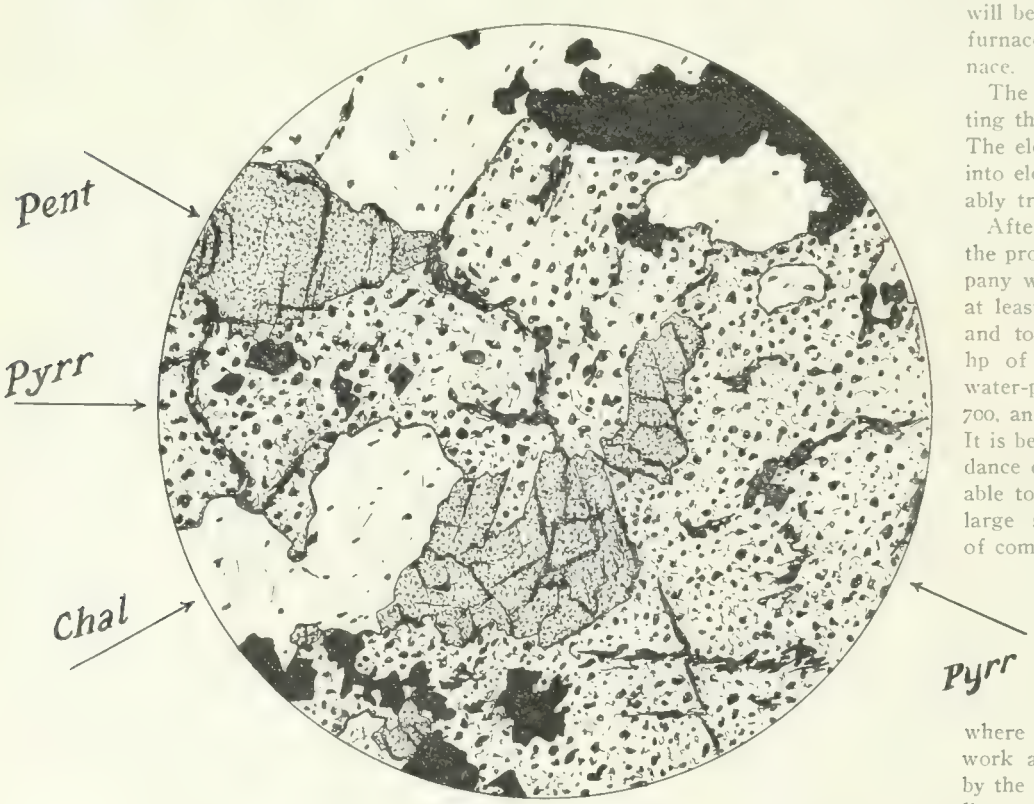
The Solubility of Cementite in Hardentite, by **Prof. J. O. Arnold** and **Leslie Atchison,** of the University of Sheffield.

On Allotropy in General and that of Iron in particular, by **Prof. Carl Benedicks,** of the University of Stockholm. The results of this paper were already given in connection with a paper by the same author, presented before the International Congress of Applied Chemistry, and abstracted in our October issue, page 692.

Occurrence of Pentlandite in the Sudbury Ores.

By F. W. Apgar and Kirby Thomas.

The micrograph herewith reproduced shows very well the occurrence and mineralogical relation of the iron nickel sulphide, pentlandite, (FeNi) S, in the typical nickel-copper bearing ores of the Sudbury, Ontario, district.



MICROPHOTOGRAPH- 62 DIAMETERS

The specimen used for this sketch was from near the footwall of the Mount Nickel Mine and shows rather more than the usual proportion of chalcopyrite. The black spots are remnants of the nickel-bearing eruptive, a norite of charactertistic type associated with the ore bodies and from which primarily they were derived by processes of magmatic segregation with probable later concentration through redeposition.

The pyrrhotite is magnetic, though feebly, and this suggests the possibility of magnetic beneficiation of the ore, but so far no commercial application of the idea has been made.

The Iron Ore Mines of Cogne (Valle d'Aosta) and the Projected Electric Pig Iron Plant.

The famous Valle d'Aosta, known by its ancient history as well as by the romantic beauty of its scenery, will give rise to a modern development of metallurgical industry. A recent issue of the "Rassegna Mineraria Metallurgica e Chimica" gives a description of the program which the "Societa miniere di Cogne" intends to carry out. There are iron ore deposits in about 16 1-4 miles distance from Aosta on the banks of a small tributary of the Dora. They are found in a height of between 6500 and 8200 ft. above sea level, which would mean about 4500 to 6000 ft. above Aosta.

The available supply of ore has been calculated as being 6,000,000 tons of the first quality, containing 60 per cent of iron, practically free from sulphur and phosphorus, and the conditions under which the new company will start operations are very promising. The following is their program: An aerial railway will carry the mineral down to Cogne with a drop of 1500 to 3000 ft. over a distance of about 2 miles. In the latter place the ore will be crushed, concentrated and brought into a pasty condition. By adding sufficient water this mixture will flow, with a drop of 5 per cent, through tubes to a place of 14 miles distance. At this place, called Aymaville, the ore concentrates will be pressed into briquettes containing 70 per cent of metal, part of which are intended to be sold in open market. The rest will be charged into electric pig iron furnaces and one ordinary blast furnace.

The process applied for briquetting the ore is the one of Groendall. The electric pig iron will be charged into electric steel furnaces and probably transformed into tool steel.

After a complete development of the program laid out so far the company will be in condition to produce at least 180,000 tons of ore per year and to obtain on an average 37,000 hp of electrical energy from four water-power stations of 19,500, 8000, 700, and 900 hp capacity respectively. It is believed that with such an abundance of power the company will be able to utilize electric furnaces on a large scale, operated independently of combustible fuels, and in this way to establish an entirely national Italian industry.

The Sherardizing process is making rapid progress in this country where there are some 34 plants at work and is being extensively used by the General Electric Company for line material. A committee of the Franklin Institute of the State of Pennsylvania have recently made a report on the process and have awarded the inventor, Mr. Cowper-Coles, of London, the John Scott Legacy Medal and Premium.

American Electrochemical Society Papers at the International Congress.

Since the American Electrochemical Society decided not to hold a special fall meeting this year in view of the Congress of Applied Chemistry, those papers which were available were presented at joint sessions of the Congress and of the Society.

In the following we give abstracts of three American Electrochemical Society papers which have not yet been reported in these columns.

Fixation of Nitrogen by Alumina and Carbon.

A paper by **Professors S. A. Tucker** and **Henry L. Read,** of Columbia University, gives the result of an investigation made to find out whether nitrogen would combine with a heated mixture of alumina and carbon or with products arising from the heating of such a mixture, and to study the best conditions for bringing about the reaction.

It was furthermore desired to investigate the conditions under which ammonia could be obtained from the resulting nitrogenous product.

That aluminium and nitrogen form a compound under certain conditions of the nature AlN or Al_2N_2 has long been known (*Zeitschr. Anorg. Chem.*, 54, 522-7, Fichte). This aluminium nitride is described as a gray amorphous powder. It is partly decomposed by water, forming ammonia, and this reaction also takes place on long standing in the air. Complete decomposition is effected by heating in alkali.

Ottokar Serpek was apparently the first to consider the possibility of applying the reaction of aluminous compounds with nitrogen to the fixation of atmospheric nitrogen. In numerous patents (U. S. A. Patents 888,044, 867,615, 987,408, 996,032; German Patents 181,991, 181,992, 183,702, 216,746; British Patents 13,579 (1906), 15,996 (1909), 25,141 (1911), in this country and abroad, he has covered the subject of aluminium nitride production, but without explaining much about the nature and conditions of the reaction. The chief point he makes is that a temperature of about 1800 deg. to 2000 deg. C. is essential, although in a more recent patent he mentions 1600 deg. to 1800 deg. C. as being permissible.

He works on mixtures of alumina or aluminous compounds with carbon, the materals being in a pulverized condition, claiming that this is better than aluminium carbide. This is in accordance with the theory of Caro (*Zeitsch. Angew. Chem.*, 23, 2412), that when aluminium nitride (AlN) is formed by heating aluminium carbide (Al_4C_3) with nitrogen, the reaction is due to the dissociation of Al_4C_3 to Al and C. Caro found in general that more nitrogen combined around 1150 deg. C. with Al_4C_3 if metallic Al was present than with pure carbide, and that the largest yield of nitrogen came when aluminium alone was heated. Very little nitrogen was obtained with pure carbide, as at this temperature the dissociation is small.

Serpek's method of producing aluminium nitride (AlN) was from bauxite and carbon passed through a revolving inclined tube in the walls of which was an electric resistance furnace. Nitrogen was passed through the tube as producer gas, and being ignited at the end of the tube, the gas is used to preheat the charge. He observed that an acid gas such as HCl or SO_2 in small amount seemed to help the reaction along, though why this should be is not exactly clear.

In the experimental work of the present authors pure nitrogen was used, obtained in the early experiments by passing commercial nitrogen through a combustion furnace containing heated copper gauze to remove the oxygen which was present to the extent of 7.2 per cent. In the later experiments, chemical nitrogen was used, prepared from NH_4Cl and $NaNO_2$. As a precaution, this too was passed over red hot copper. Thorough drying was effected by calcium chloride and concentrated sulphuric acid. These precautions were thought necessary, as oxygen would obviously have a bad effect by diluting the nitrogen, and by oxidizing the carbon in the charge; and water would absorb heat, and tend to increase the loss of carbon in the charge forming hydrocyanic acid. It was found that cyanogen formed in any case, but water increased the amount. Purified alumina was used, and the purest grade of petroleum coke, in all experiments except those on bauxite.

The bauxite used gave on analysis: SiO_2, 5.10 per cent; Fe_2O_3, 1.56 per cent; Al_2O_3, 53.76 per cent; ignition loss, 31.07 per cent; other substances (by difference), 8.50 per cent. From this the amount of Al_2O_3 in the residue after ignition was 78.00 per cent. The very large ignition loss is explained by the fact that bauxite contains a large proportion of water.

The first experiments of the authors were made in a wire-wound electric resistance furnace. In order to get higher temperatures they later employed a granular carbon furnace through which a tube passed for holding the charge, heated by a single-phase alternating current. At first several porcelain tubes were used, imbedded in the granular carbon resistor (Fig. 1). These porcelain tubes were found, however, inade-

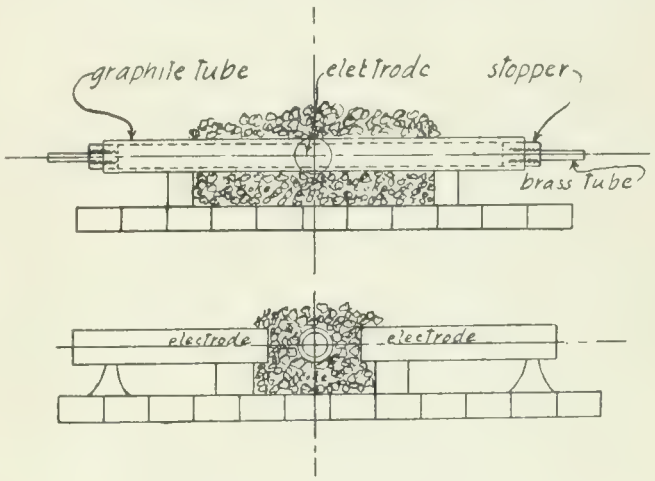


FIG. 1.—VERTICAL SECTION OF FURNACES.

quate to stand the sudden changes in temperature. The difficulty was overcome by using a graphite tube which was made with a bore of ⅝ in. diameter. The tube was provided with accurately fitted stoppers of graphite through which the nitrogen could be passed through metallic tubes threaded into the stoppers. The charge was contained in a graphite boat.

The chief results are as follows:

Aluminium nitride (AlN) may be formed from Al_2O_3 and C in atomic ratio 1:3 or 1 part by weight of Al_2O_3 to 0.353 parts by weight of C. These would be the natural theoretic proportions from the equation.

$$Al_2O_3 + 3C + N_2 = 2AlN + 3CO$$

and they seem to be borne out by the experiments. Whenever the yield of nitrogen approached the theoretical 34.06 per cent the product was a nearly white amorphous substance with occasional particles of undecomposed carbon.

The temperature at which the reaction is carried on is evidently of prime importance. At lower than 1600 deg. C. the yield of combined nitrogen is trifling. Around 1800 deg. to 2000 deg. C., however, seems to be the right value as here was obtained the maximum amount of combined nitrogen, 30.19 per cent. But it is unsafe to go above 2000 deg. C. since decomposition of the nitride is liable to take place.

The time required for the reaction is comparatively short, but it is clear that there is a limit below which the reaction is incomplete as shown by two runs, 8 and 9, which were carried out under exactly the same conditions except that the former was strongly heated 15 minutes and the latter 30. The nitrogen in 8 was 6.11 per cent and in 9 was 9.57 per cent.

When there are impurities present, a greater length of time seems necessary. The question of impurities is very interest-

ing, as little is known about their effect. SO_2 in appreciable amounts is evidently harmful. Whether in minute traces, such as would be obtained in the producer gas from a good coal, the effect might not be better than appeared in this work of the authors is, of course, an open subject, but from a theoretical standpoint there would seem to be little reason for its use. The same would apply to HCl.

Producer gas as a source of nitrogen might be highly advantageous owing to its ability to burn and preheat the charge after it had been used in the reaction; and the further condition that oxygen should be absent is satisfied. Of course, the CO would have the effect of diluting the N, but the harm should not be serious with a plentiful supply of gas.

But impurities in the charge itself are apparently very useful, as is seen in the results on bauxite. This is probably due to catalytic action, of iron and lime particularly. It would seem that the effect of heating Al_2O_3 with C is first to produce nascent Al, which under ordinary conditions forms Al_4C_3.

But in the presence of fairly pure nitrogen the aluminium seems to have a greater affinity for nitrogen than for carbon. This would appear to agree with Caro's theory that aluminium carbide heated with nitrogen forms aluminium nitride by the dissociation of the carbide, after which the aluminium attaches itself to N. This is contrary to the former opinions of some writers who hold that it was the formation of the carbide that was a necessary preliminary to the formation of the nitride. But if the above theory is correct, obviously catalytic agents would be highly desirable, and they should be substances that form nitrogen compounds without great difficulty.

Another highly important point is that the gas should have means of easily getting in contact with the charge. Fairly fine crushing would seem to be a necessary condition for best results. Serpek's method of bringing about this contact was by the rotating cylinder previously mentioned. He would have the difficulty of obtaining a substance for the lining of this cylinder which could stand the high temperature and the abrasion of the charge passing over it. Carborundum might do it; so might silundum; possibly also magnesite, though it would undoubtedly wear out fairly rapidly.

As to the value of aluminium nitride as a commercial product, the ease with which ammonia can be formed is obviously the most important feature. It is well known that boiling alkaline solutions decompose it completely. Thus a source of commercial ammonia is evident, and connected with it a source of pure alumina that might well interest manufacturers of aluminium.

So far as its use as a fertilizer itself is concerned the last test described with the curve shows that it gradually evolves the nitrogen as ammonia from boiling water. If applied directly to the soil it might be expected to behave in a way not very different from this, which so far as its value as a fertilizer is concerned would be an advantage. The raw material bauxite is, however, probably too expensive to permit of its use in this manner and the nitrogen would have to be obtained as ammonia, so that the by-product alumina could be saved, either to use again in the process or in the manufacture of aluminium.

From the results of the necessarily brief set of experiments given, it is clear that, given suitable conditions, there should be no difficulty in producing a grade of aluminium nitride containing 30 per cent and more nitrogen. This should give the product an advantage over calcium cyanamid, which on the average runs from 17 per cent to 20 per cent fixed nitrogen.

Electric Resistivity of Fire Bricks at High Temperatures.

A paper by Prof. **A. Stansfield** and Messrs. **D. L. McLeod** and **J. W. McMahon** gives the results of experiments made at McGill University.

The materials tested were Caledonia firebrick, Star silica-brick, magnesite-brick, and chrome-brick, the last three being obtained from the Harbison-Walker Refractories Company. Cylinders 2 in. in diameter and about 2½ in. long were cut from these bricks, the length of the cylinder being the thickness of the brick. These cylinders were supported between disks of graphite of the same diameter, and contact was made between the cylinders and the disk by means of a paste of graphite and glue. In the first few experiments the apparatus was heated in a gas furnace, but this method of heating was found unsatisfactory, and electrical heat was then employed.

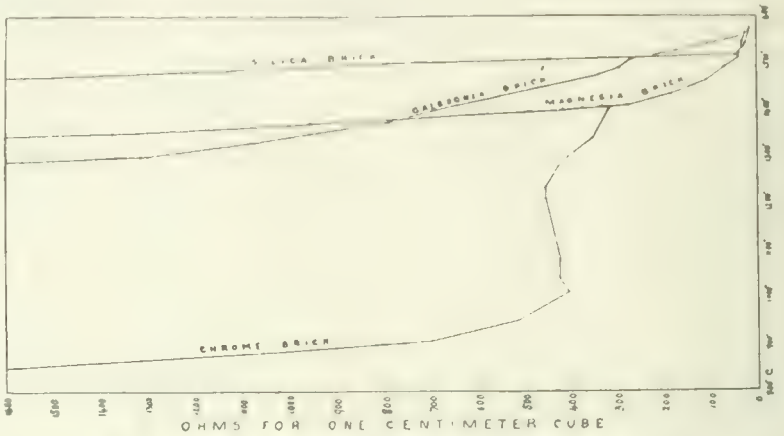

FIG. 2 CHART OF ELECTRIC RESISTIVITY OF FIRE BRICKS.

The results obtained from these experiments have been tabulated, and are also shown, in part, as curves in Fig. 2. It will be seen from these that at 1500 deg. C. the resistivity of all these materials is somewhat low. Comparing the results for the different materials, it wil be noticed that the silica and magnesia bricks, which approximate most closely to pure oxides, retain their insulating qualities to high temperatures, no considerable current being obtained below about 1300 deg. C. The firebrick and chrome brick, on the other hand, which are more complex in composition, begin to conduct at considerably lower temperatures. At the highest temperatures observed, about 1550 deg. C., the resistivities of all the bricks tested were about the same, being about 25 ohms for a 1-cm cube.

The accuracy of the readings was not very great, being limited by that of the ammeter for high resistivities and by that of the voltmeter for low resistivities. It is possible that the combined error would not be more than 5 per cent or 10 per cent for most of the readings, but increasing in the case of the higher figures, above 6000 ohms, to a maximum error of about 25 per cent at 21,000 ohms. It is doubtful whether the higher temperature readings are to be depended on within about 20 deg. C., although the relative error in the readings would be less than this.

The results obtained for the chrome brick are very peculiar. This was not noticed until it was too late to repeat the observations, and they should therefore be regarded as subject to correction.

In connection with these results it is interesting to allude to a few figures which have already been published in this connection. Reference may be made to a paper by H. M. Goodwin (*Transact.*, Am. Electrochem. Soc., Vol. 9, p. 89, 1906) on the physical properties of fused magnesium oxide. The electrical resistivity of this oxide was tested and was found to be 380,000 ohms for a centimeter cube at 1150 deg. C., which was the highest temperature reached. Landlot and Börnstein give the resistivity of magnesia at 1500 deg. C. as 12,000 ohms for 1 cm. cube, and that of zirconia as 1200 ohms at 1200 deg. C. These figures are very much higher than the authors have obtained for firebricks, but it may be mentioned that $MgO + 10$ per cent B_2O_3 at 1250 deg. C. has a resistivity of 83 ohms. On

the other hand, porcelain at 1000 deg. C. has a resistivity of 330,000, according to Nernst-Reynolds, and Goodwin gives values of 1,000,000 ohms at 1000 deg. C. and 780,000 ohms at 1100 deg. C., which seem very high in view of the figures the authors obtained for firebrick.

The results give the averages of a number of tests which were in most cases quite concordant. It would be desirable to extend the work to higher temperatures and to use test-pieces of different dimensions.

Electrolytic Refining of Silver-Bismuth Alloys.

A paper by Dr. **William N. Lacey** gives the results of an experimental investigation carried out at Leland Stanford University on the electrolytic separation of silver from bismuth from the binary alloys.

Three alloys were made; A containing 65 per cent of silver and 35 per cent of bismuth; B, 2.8 per cent silver and 97.2 per cent of bismuth, and C 53 per cent silver and 47 per cent bismuth.

Electromotive force determinations were made for alloys "A" and "B" in each of the two electrolytes, *i. e.*, cyanide of silver and nitrate of silver, using metallic silver as the other pole of the cell. The results obtained are shown in the following tabulation:

Electrolyte.	Positive Pole.	Negative-Pole.	E.M.F. of Cell—Volts.
Cyanide	Alloy "A"	Silver	0.202
Cyanide	Alloy "B"	Silver	0.242
Cyanide	Bismuth	Silver	0.173
Nitrate	Silver	Alloy "A"	0.591
Nitrate	Silver	Alloy "B"	0.448
Nitrate	Silver	Bismuth	0.288

"The difference in polarity of the two alloys in the two solutions is probably due to the fact that there are relatively few silver ions present in the cyanide electrolyte as compared to the nitrate electrolyte. The lower results obtained in using pure bismuth may be accounted for by heat being absorbed in the formation of the alloys, thus giving them a higher emf."

Experiments were then made on the separation of the silver from the bismuth using either a cyanide electrolyte or a nitrate electrolyte.

The "cyanide electrolyte" was prepared by adding a 5 per cent solution of potassium cyanide (KCN) to a 5 per cent solution of silver nitrate ($AgNO_3$) until the precipitate dissolved. Just enough of an excess of cyanide solution was added to keep any silver cyanide from forming during the electrolysis.

The "nitrate electrolyte" is the one used in the United States Mint at San Francisco in the electrolytic refining of silver bullion. It was a solution containing 3 per cent silver, as silver nitrate, and 2 per cent of free nitric acid.

The results of these experiments are given in extended tables and diagrams. The chief conclusions are summed up as follows:

Results Obtained with the Cyanide Electrolyte:

(*a*) A deposit of silver containing less than 1 per cent of bismuth may be obtained by using a current having a normal density of 100 sq. cm. of not more than 0.14 amp. The current density gradually decreases during the electrolysis. All current density results are approximate, due to the uncertainty of cathode surface measurements.

(*b*) The potential difference between the electrodes gradually increases through a small range, during the electrolysis, but may safely be as high as 6 volts.

(*c*) The required energy input is about 0.25 kw-hour per pound of silver deposited for a potential difference of 1.5 volts. This value is increased by 0.11 kw-hour per volt of increase in the potential difference.

Results Obtained with the Nitrate Electrolyte:

(*a*) The silver deposits had comparatively high bismuth contents, even for low current densities. The results showed no great regularity.

(*b*) The potential difference between the electrodes must be kept down almost to the emf force of the cell in order to get a good separation.

(*c*) The required energy input, expressed in kw-hours per pound of silver deposited, is about 0.06 for a potential difference of 0.5 volt. There is an increase of 0.15 kw-hour for an increase of 1 volt in the potential difference.

Comparison of the Two Electrolytes:

(*a*) The nitrate electrolyte demands a weaker current, which calls for a much larger electrode surface for the same rate of deposit.

(*b*) The percentage of bismuth in the cathode deposits is more irregular and uncertain for the nitrate electrolyte, possibly due to colloidal conditions in the anode slimes.

(*c*) The necessary energy input increases more rapidly for higher voltages in the nitrate electrolyte than in the cyanide electrolyte.

(*d*) The deposit from the cyanide electrolyte is quite adherent, and the use of anode bags is avoided. The bismuth content of the deposit, using the cyanide electrolyte, is small enough to be gotten rid of in the melting, without occasioning a large loss.

Causes of the Practical Non-Success of Electric Furnaces in Treating Zinc Ores.

BY FRANCIS LOUVRIER.

For years past the application of electrical energy to the economical treatment of ores has been the desideratum the most sought after. Especially is this the case with respect to the electrical treatment of zinc ores, due to the high cost and the low yield of the present process.

The success of the inventors so far, however, seems not to have been commensurate with the time, study, research, and experiments devoted to it, as, until now, no electric furnace has given sufficiently satisfactory results to warrant its adoption as an economical substitute for the present method, and that despite the latter's numerous defects.

This lack of success seems somewhat inexplicable, especially as, excepting the manner of heating the ores (externally in the present system, internally in the electric furnaces), the inventors of the latter have copied the actual process of distilling the zinc, as well as adopting the same chemical reactions as developed in the ordinary retorts, which yield sufficiently satisfactory results.

Notwithstanding this, however, all experiments undertaken so far have been characterized by an unsatisfactory condensation of the zinc vapor, a considerable portion of the zinc obtained being produced in the form of blue powder instead of molten metal. This fact of the production of blue powder which does not take place in the ordinary retorts, or, if it does, in very small quantities, is due to the formation in the electric furnaces of a much higher percentage of carbon dioxide than in the usual retorts.

Although the various inventors and experimenters may have believed that in their experiments they fulfilled all the con-

ditions to which the zinc oxide is submitted in the ordinary retorts, the different results obtained prove the contrary.

As in this case, the electric current is "chemically neutral" and does not affect the reduction of the zinc oxide, it must be deduced that the conditions to which the same substances are submitted are different in each case. To ascertain of what this difference consists, research has been undertaken by the writer, with the result that he has arrived at the following conclusions.

It is well known that, in accordance with the formulas given hereunder, two operations take place in the reduction of zinc ores:

$$(1)\ ZnO + CO = Zn + CO^2$$

$$(2)\ CO^2 + C = 2CO$$

The final products are zinc in the form of vapor, and carbon monoxide; but there is an intermediary production of carbon dioxide, which, in the presence of carbon at a high temperature, reacts to form carbon monoxide, this latter reaction taking place at a lower temperature than the former.

In an ideal reduction all the carbon dioxide should be converted into carbon monoxide. Unfortunately, in practice, this is not the case, and especially not in electric furnaces, in which, in every instance, there has been found the formation of a high percentage of carbon dioxide mingled with the zinc vapor. It is clear that this high percentage is the result of the incomplete manner in which the last named reaction occurred, i.e. the transformation of carbon dioxide into carbon monoxide.

This, therefore, induced us to investigate the causes which create this incomplete transformation.

In ordinary retorts, due to the slowness in which the reduction of the zinc oxide is effected, and to the slight production of carbon dioxide which results from it, as well as to the uniformity of temperatures, the conversion of the carbon dioxide into carbon monoxide takes place almost completely and without difficulty, *because the contact of the carbon dioxide with the hot carbon reducer occurs during a relatively long period.* The result is, therefore, that there passes to the condenser, mixed with the zinc vapor and the carbon monoxide, a very small percentage of carbon dioxide, insufficient to alter in any way the zinc vapor or create any disturbance in the condensation.

In the electric furnaces that have been used to experiment with the treatment of zinc ores, the conditions under which this conversion took place, are different, as will be shown later. To date, these furnaces have been either of the arc or the resistance type. In this last named class the current passes through a resistor constituted either of carbon, or a bath of slag, or between two electrodes dipping into the charge to be treated. In each case the furnace had a zone directly heated by the current and very limited, which consequently, was at a much higher temperature than that required for the reduction of the zinc oxide.

If the furnace had a relatively large capacity, the part outside of the zone traversed by the current would have remained at a comparatively low temperature; so that the following took place:

Within the directly heated zone, the reduction of the zinc oxide took place rapidly and was accompanied by a great production of carbon dioxide which, escaping to the higher part of the furnace, almost immediately entered a comparatively cold zone, too cold to permit, when it came into contact with the carbon, its complete transformation into carbon monoxide. The consequent result was that only a small portion of the carbon dioxide was converted into carbon monoxide, due to deficient contact with the hot carbon reducer.

In other electric furnaces in which experiments were made their capacity was too small, the entire contents being carried into a strong incandescence, so that the carbon dioxide resulting from the reduction of the zinc ores encountered, while escaping, an insufficient quantity of carbon, as well as too high a temperature, to permit its complete and normal transformation into carbon monoxide.

From these considerations the following conclusion is arrived at:

The [illegible] dioxide, in [illegible], in the actual electric furnaces is due, at least in its greatest part, to the rapidity in which the reduction of the zinc ores takes place, which creates a too active production of carbon dioxide in a limited space, so preventing this gas from coming into contact with the carbon reducer during the time required for its reduction. This rapidity is caused by the too high temperature which results from the smallness of the zone in which the effects of the electric current are directly felt.

Be this the case, the amount of carbon dioxide and, consequently, the quantity of blue powder produced in electric furnaces, must be in proportion to the maximum temperature in the furnace. This is precisely what actual electric practice has demonstrated, seeing that the arc furnaces produce more blue powder than the resistance furnaces, and in these latter, when either accidentally, or from lack of care, an arc is formed, a disturbance is at once perceived, which is accompanied by a more abundant production of blue powder.

Another fact tends to confirm the accuracy of our assumption. In all experiments made to date with electric furnaces, the presence of notable quantities of carbon and ore dust in the condensers has been observed. As the presence of carbon and ore dust can only be explained by an outrush of gas and vapor strong enough to carry out this dust, it must necessarily be admitted that the production of gas and zinc vapors is too rapid in the furnaces, and that, therefore, the contact of the carbon dioxide with the carbon reducer cannot take place during the time required to convert it into carbon monoxide.

Furthermore, other causes contribute to increase the percentage of carbon dioxide in the electric furnaces, as, for instance, the vertical disposition of the movable electrode. It is clear that the reduction of the zinc oxide is more active where the temperature is highest, that is, in the zone in contact with the electrode. Consequently, in the immediate vicinity of the electrode the production of carbon dioxide is particularly abundant. As the electrode operates within a small open or free space (formed to permit its movement, as well as naturally, by the descending charge which is coning down toward the electrode) a notable quantity of the carbon dioxide produced escapes through this free space without meeting any of the carbon reducer to transform it into carbon monoxide.

Various methods have been suggested and attempted to prevent the formation of large quantities of carbon dioxide in electric furnaces. These consist in forcing the gases and vapor, which escape from the furnace, to pass through a column of incandescent carbon. These remedies, however, have not given any radical results. They have the defect of working too tardily, and, therefore, are only palliatives. It is in the furnace itself, not outside of it, that the conversion of the carbon dioxide into carbon monoxide must take place.

The inevitable deduction from the foregoing is that the high percentage of carbon dioxide found in the electric furnaces used until now is due entirely to the ineffective disposition of these furnaces, which are not arranged to allow the performance of the necessary chemical reactions. As these reactions yield sufficiently satisfactory results in ordinary retorts, the fault evidently lies in the defective physical arrangements of the electric furnaces in which the experiments were made. To remedy these defects seems more to lie within the province of the electrician than the metallurgist. The remedy would therefore appear to come in devising some new manner of conducting the electric current in the furnaces, and dividing the current as uniformly as possible among all the charge contained in the reduction zone of the furnace, instead of

concentrating it, as at present, in the confined space comprised between the two electrodes.

We are thus led to indicate the improvements that are necessary to render the electric furnace efficient, or, rather, the conditions to be filled.

1. An electric furnace to treat zinc ores must contain a zone of reduction in all parts of which the temperature must be more or less uniform, but not too high, so that the reduction of the zinc oxide may take place slowly and with equal intensity in any horizontal section of the furnace.

2. This zone of reduction must be large enough to compel the zinc oxide to remain at the necessary temperature during the time required for its complete reduction, which must be effected as slowly as possible, and as well permit the slow escape of the carbon dioxide, so that it may enter into contact with the hot carbon for the time necessary to transform it into carbon monoxide, and, furthermore, prevent any outrush of gas and vapor which would be capable of carrying dust into the condensers.

3. The height of this reduction zone must be sufficiently great to permit the carbon dioxide to be entirely converted into carbon monoxide in meeting, on its escape, a layer of ore and carbon at the necessary temperature, and, above all, thick enough to allow a sufficiently long contact.

4. The temperature in the reduction zone (principally when treating complex ores containing other metals, such as lead or copper), although uniform in a horizontal section, should be gradually increased as the floor of the furnace is reached, in order that the reduction zone of the zinc oxide may not be the same as the reduction zone of the lead and copper.

This can be practically thus obtained: the upper part of the reduction chamber being more or less at 1050 deg. centigrade, i.e. at the reducing temperature of the zinc oxide, while the lower part remains at 1200 deg. or 1250 deg. centigrade, the normal temperature for the reduction of lead or copper ores.

In this way the carbon dioxide resulting, for instance, from the reduction of the lead ores, has to traverse a thick layer of charge containing the hot carbon, which transforms it into carbon monoxide before mingling with the zinc vapor formed in the upper part of the reduction zone.

5. In the zone of reduction there should be no free space through which the carbon dioxide can escape without first having come into contact with the hot carbon reducer. This, as stated, will exclude the employment of movable vertical electrodes inserted into the charge to be treated.

Besides these essential conditions, conditions which in the furnaces hitherto employed have never been realized, it is clear that, with a furnace adapted to treat zinc ores, it must also fulfill the following requisites:

(a) It must be completely closed to prevent the entrance of air, at least in the reduction zone.

(b) It must be arranged in such a way that the charge will reach the reduction zone already sufficiently heated so that all water, air, etc., have been completely expelled.

(c) The carbon monoxide produced should be recovered, so that it may be again utilized, as, for instance, to roast the ores when these are blende or calamine.

(d) It must be arranged for continuous working.

We do not conceal from ourselves the difficulties to be overcome in establishing a furnace that will meet the conditions indicated above. But as to know the causes of an evil is to have effected half its cure, so we have thought that by exposing the origin of the defects, as these appear to us and as outlined above, we may have indicated the paths to be followed, to encounter, finally, a practical solution of the perplexing problem, How to secure the economical treatment of zinc ores.

Mexico City.

Notes on Chemistry and Metallurgy in Great Britain.

(From Our Special Correspondent.)

The British Association.

The eighty-second annual meeting of the British Association which was opened at Dundee on September 4 will probably rank as one of the most memorable gatherings of scientists. The attendance on the first day, when Professor Schafer delivered his address on the nature, origin and maintenance of life, considerably exceeded all previous figures and numbered 2379.

In his presidential address to the Engineering Section Professor Archibald Barr advocated a "closer connection than was usually recognized between the work of the engineer and that of those to whom the title of artist was usually restricted; and in addressing the Chemical Section Professor A. Senier emphasized the value of research work and the advantages of providing greater facilities for its prosecution by capable men. "The object and ideal," he said, "is wrong also in our system of technical training. We aim too much at giving elementary instruction to artizans, which, though important in itself, can never take the place of the higher education of leaders or managers of industrial works." In the Mathematical and Physical Science Section Professor Callendar dealt with what he termed the "re-discovery of caloric," and said it would be advantageous to supplement the kinetic theory of heat with some of the ideas of the old—he should have said "exploded"—material caloric theory. Not content with this, he proceeded to express a preference for regarding *molecules* of caloric as being composed of positive and negative *corpuscles* of electricity, *"in much the same way as a molecule of hydrogen is formed by the union of two atoms."* He further actually spoke of the *weight* of "caloric." Unpalatable as this attempt to treat force as a material substance must have been to most, if not all, physicists present, yet his eulogy of Carnot was received as a worthy tribute. After this it was not greatly surprising that Professor Bragg, in an evening address on "Radiations, Old and New," should have expressed the opinion that Newton's *particles* of light might, perhaps, be discovered in the emanations from radio-active matter, and that it was not impossible that modern science would draw together the corpusclar and wave theories of light.

Truly, the study of radio-activity is bringing forth a promise of rare and refreshing fruits. Will they prove better than Dead Sea Apples?

Deterioration of Aluminium Alloys.

In the Engineering Section of the meeting of the British Association at Dundee early in September, Professor Ernest Wilson read a report on "Exposure Tests of Light Aluminium Alloys." He said that reports presented to the British Association during the last eleven years showed that alloys of commercial aluminium with copper only were not satisfactory, and a 2.6 per cent copper alloy had completely deteriorated in ten years, and its electrical resistance had increased 25 per cent. The alloys under investigation were in the form of wire, 0.126 in. in diameter, and were suspended on the roof of King's College, London, to ascertain the effect of such exposure on their electrical conductivity. The addition of iron, nickel and manganese to the low copper alloys had been found to increase both the tensile strength and the resistance to deterioration. With specimens containing, respectively, 1.16 per cent of iron, 2.25 per cent of nickel, and 1.78 per cent of manganese the electrical resistance had only increased about 9 per cent in eleven years. "Duralumin" was a copper-manganese-aluminium alloy, plus about 0.5 per cent of magnesium, and after one year's exposure a specimen, some 80 ft. long, had increased 5.15 per cent in electrical resistance. Was this due to the comparatively high percentage of copper (3.5 to 5.5) or was the manganese (0.5 to 0.8) too low? By suitable treatment this alloy could be obtained with a very high breaking load—up to 90,000 lb.—but its electrical specific resistance was about twice that

of commercial aluminium. The electrical resistance of high conductivity copper had been found to increase only 1.2 per cent after one year's exposure.

In the discussion, Mr. Arnold Lupton asked if there were any notable amount of salt in the atmosphere at King's College. It was well known that the destructive effect of salt on aluminium and its alloys was very great.

Professor Petavel asked if tests had been made of the effect of exposure on the mechanical properties of the specimens. Such tests would be very valuable to aviators who were inclined to give up these light alloys and revert to steel, in spite of its weight being five times as great, not because it was known that these alloys would deteriorate say 10 per cent in a year, but because there was uncertainty as to the extent to which their uniformity could be relied on. A known depreciation could be allowed for; but the irregularity in the properties of many alloys was a more serious matter. Duralumin at its best might have the lightness of aluminium with the strength of steel; but unfortunately it was extremely sensitive to heat treatment. The difficulty of soldering aluminium was a source of trouble, and there was danger that moisture might cause rapid deterioration at the joints.

Professor Wilson replied that the atmosphere at King's College was practically free from salt but contained sulphur. It was recognized that aluminium deteriorated rapidly in the neighborhood of salt water, and was unsuitable for power transmission lines in such situations. He regretted that the limited number of his specimens, which he did not wish to destroy, had not allowed him to take physical tests. He agreed that there was danger in soldered aluminium joints, and deprecated the use of any other metal than aluminium alone for jointing.

In connection with this subject your correspondent would point out that, as far as is known, attention was first drawn to the spontaneous disintegration of aluminium alloys by the late Sir W. Roberts-Austen in the Third Report of the Alloys Research Committee, which embodied the results of his research in 1895 on the melting points of the iron-aluminium alloys. In a paper read before the Faraday Society in June, 1910, on "The Failure of Light Engineering Alloys, particularly the Aluminium Alloys," E. F. Law stated that it had since (1896) been shown that spontaneous disintegration occurred with most of the other aluminium alloys, including those with nickel, cobalt, antimony, manganese, molybdenum and even zinc. He established the fact, which Roberts-Austen does not appear to have observed, that disintegration is preceded by marked expansion; and went on to say, "It is interesting to note that chilling appears to prevent the disintegration. A particular alloy was found to disintegrate in three weeks when allowed to cool in the crucible, whereas samples of the same alloy, made at the same time, and with the same materials, but cast in an iron mould, have been in the author's possession for eight years and show no signs of disintegration." It is now recognized that disintegration may, in some cases, be prevented or greatly retarded by putting work upon the alloys soon after their manufacture.

Dr. Rosenhain's researches on the aluminium-zinc alloys published in the last-issued Report of the Alloys Research Committee throw further light on the matter; but—as your correspondent remarked soon after the report was published—the statement in the text that the alloys did not appear to undergo change of properties with ageing is not consistent with the tabular test figures given.

Engineering Imports and Exports.

The returns issued by the Board of Trade for the eight months ended on August 31, show a satisfactory all-round improvement as compared with the figures for the corresponding period of last year. Imports of iron and steel, including manufactures, are valued at £8,062,227, an increase of £692,553; and exports are put at £29,896,894, an increase of £1,291,854. Other metals, including manufactures, were imported to the value of £19,893,807, and exports reached £7,498,416, the respective increases being £1,733,274 and £426,667. In electrical goods the imports amounted to £921,807, an increase of £34,592, and exports were £2,712,414, an improvement of £930,894. Imports of machinery reached £4,506,817, an increase of £522,148, and exports touched £21,181,719, a rise of £764,257. Imports of new ships totaled only £24,907, showing a decrease of £31,889, while the exports were £3,712,249, a gain of £8,768. The returns for August taken by themselves against those for August, 1911, give an increase of £316,090 in imports of iron and steel, and a rise of £937,527 in exports; imports of other metals were £630,322 higher and exports improved by £265,376; in electrical goods imports rose £11,177 and exports were £113,281 better; machinery imports went up £116,087, and exports increased by £268,584; ships show an increase of £635 in imports and exports rose £94,360.

The Use of Compressed Oxygen in Estimating Carbon in Ferro-Alloys.

P. Mahler and **E. Goutal** (*Compt. Rend.*, 1912, 154) have succeeded in estimating the carbon in the most refractory ferro-alloys by the calorimetric bomb method. In addition to the litharge flux required for very hard steels these alloys demand an auxiliary combustible, and the authors employ iron of ascertained carbon content. In the case of very high carbon alloys more than 0.5 gr. would be an inconvenient quantity, and the amount of added iron must be increased to bring the total charge to about 3 gr. in order to avoid difficulty in securing complete combustion, while the litharge used should be half the weight of the combustible charge. A determination without any alloy is made to ascertain the correction for the carbon in the additional iron and for constant errors.

The carbon dioxide is absorbed by sodium hydroxide and its amount is determined by titration before and after the combustion. The authors' results go to show that when this method gives figures appreciably differing from those obtained by direct dry combustion the figures are always higher. For instance, a 69 per cent ferro-chrome gave 9.7 per cent of carbon by direct combustion, and 10.6 by the bomb method; a 75 per cent ferro-silicon gave 0.11 per cent by the direct method and 0.2 per cent with the bomb. The authors consider that with these alloys their higher figures are probably more trustworthy. Ferro-molybdenum and ferro-vanadium give very concordant results by both methods.

Market Prices.

Copper opened at £78-18-0 and remained steady to rather lower during the first half of the month, since inclined to improve, and closes at £79.

Tin opened at £218-5-0 and was up to £226-10-0 on the 16th and 19th, reached £228-10-0 on the 24th, and closes £231.

Lead opened at £20-15-0 and rose to £23-5-0 by the 10th, afterwards easing slightly, but still at £23 on the 19th; quieter towards the end of the month, it closes at £22-15-0.

Cleveland was 63/7 at commencement of the month, 65/- on the 7th and 67/6 on the 19th; had eased to 67/1 by the 24th and closes at 67/6.

Haematite has risen during the month from 77/9 to 81/9.

Scotch Pig has also risen considerably from 67/7 to 72/9.

Recent Chemical and Metallurgical Patents.

Iron and Steel.

Briquetting.—WARREN R. VALENTINE of Ford City, Pa., has patented a method of briquetting borings, turnings, etc., for charging into furnaces, mainly cupola furnaces, in such a way that the briquets do not disintegrate before the metal melts. The binder remains effective as such up to a temperature equal or approximately equal to the melting point of the metal. The same binder can also be used with beneficial effects in forming briquets from ores and other material where integrity of the briquet at high temperature is required. The borings, etc., of iron, steel, etc., are first mixed with a finely divided fluxing material as limestone, fluorspar, etc., in the proportion of 50 lb. of flux to a ton of the material. This mixture is dampened with a solution of glutrin and soda ash or other material capable of combining with the rest with the generation of heat. While the bond is effected the temperature goes up to 100 deg. F., if the briquets have a large radiating surface, and up to 150 deg. F. in from 24 to 36 hours, when piled together. This internal heating makes the briquets hard and capable of being charged into a cupola without the employment of external heat. From 10 per cent to 15 per cent of these briquets can be charged with the heat, in ordinary foundry practice as high as 30 per cent and with light castings as high as 20 per cent can be used. (1,024,428, April 23, 1912.)

A method of reducing iron ore has been patented to the well known Swedish inventor GUSTAF GRÖNDAL. An inclined cylindrical furnace rotates and carries the intimate mixture of iron ore and carbon against the uprising flow of heating gases. These gases can, but need not be, of a reducing character in which case the amount of solid carbon can be decreased. In case the gas or gas mixture is chemically indifferent and merely acts as a carrier of heat (at about 800 deg. C.), the best proportion of carbon has been found to be 20 per cent of the iron contained in the ore. The mixture is preheated and dried by part of the used gases and fed into the rotating tube by a screw conveyor. At the lower end of the furnace the iron drops automatically into cars on trucks. The reduction process increases the amount of gases passing through the furnace and the excess is led away and used for heating the recuperator at the discharge end of the system. The heating of this recuperator, however, is principally effected by producer gas specially produced for this purpose. The bulk of the gases is forced by a blower through the recuperator and back into the furnace. The furnace and various ways of connecting the gas mains are illustrated by drawings. (1,033,051, July 16, 1912.)

Converter-Electric Steel.—The old idea of accomplishing the oxidizing and the electrical refining of steel in one and the same furnace is brought forth in a new variety of apparatus by HENRY JOHNSON, Sheffield, England. A double-ended converter of approximately cylindrical shape adapted to be rotated end over end is suspended in trunnions and provided with tuyers at one end. These tuyers passing through the side or through the end itself may be horizontal or vertical. The other end of the converter is fitted with means for refining and finishing, for instance, a number of electrodes connected to direct or alternating single or multiphase current. The converter is rotated about an axis which is at right angles to that of the vessel in order to bring either side into operative position. Charging and teaming in the usual way are described in detail. (1,032,217, July 9, 1912.)

Hot-Blast Stove for Heating Air, Steam or Other Gases.—The present hot-blast stoves used in heating the air for blast furnaces suffer much from alternate heating and cooling of the firebricks and consequent expansion and contraction. The highly heated flues are liable to lose shape and soot settles on all possible surfaces of the brickwork. FRANK C. ROBERTS of Wynnewood, Pa., has designed several shapes of bricks intended to overcome this trouble and to allow a quicker cleaning out of the stove. His bricks show recesses and projections of same thickness as the brick itself, either recess and projection on each brick or only two projections or only recesses. A number of cuts illustrate the variety of ways to join the different bricks (one type at a time in one furnace) together. (1,032,505, July 16, 1912.)

Purifying Iron and Manufacturing Steel.—Three patents have been granted to HERMAN A. BRASSERT, application for which was filed as early as November, 1904. The main feature of all three inventions is to run the iron from a blast furnace into some vessel, preferably of a size large enough to hold from 50 to 200 tons of metal. This vessel is provided with tuyers, through which the hot blast or cold blast can be directed onto the surface of the metal. By means of this blast the sulphur, phosphorus, silicon and if so desired, the carbon can be removed. The heats developed by these reactions is sufficient to keep the metal liquid, in fact the heat is sometimes increased beyond the requirements, and it is necessary to regulate the pressure of the blast, or to use the cold blast instead of the hot one. By thus regulating the air blast the heat of the bath can be varied at pleasure. This offers means to oxidize the phosphorus at the low temperature which is desirable for this purpose. It is claimed that by using the above described process, iron can be purified and afterwards used for steel making in a more rapid way than known before, or the iron can be transformed into steel in one operation in this same vessel. The inventor thus intends to dispense entirely with the use of converters, mixers, and open hearth, and with the different operations of transferring the metal in ladles from one furnace to another. (1,032,653, 1,032,654, 1,032,655, July 16, 1912.)

Disintegrating Nodulizer-Kiln Rings.—When pyrites cinder, fine iron ore, furnace flue dust, and the like are agglomerated in a rotating nodulizing kiln, there is a tendency for the material to form a ring within the kiln near the discharge end. If this ring is allowed to grow it will ultimately prevent the discharge of material from the furnace, and some means must be adopted to break it. In Fig. 1 we illustrate a device for this purpose, patented by Mr. JAMES W. SHOOK, of Tuscaloosa, Alabama. The figure shows the discharge end of a kiln, and two views of the disintegrating harpoon.

The ring of furnace stock is shown at *F*. The harpoon *H* has a chisel edge attached to a supply pipe *G*, which has a flexible connection *J*. Discharge holes *KK* are placed in the bottom face of the harpoon. To remove a ring of sintered material the disintegrator is passed through one of the port holes in the hood *D* and the chisel edge of the harpoon is forced under the thin edge of the ring against the brick lining *E*. At the same time a stream of water is forced through the supply pipe

and out of the holes AA. The sudden vaporization of the water breaks the ring and this process is repeated until a cut is completed across the ring, after which the rotation of the kiln will shake the remainder of the ring loose. (1,035,754. Aug. 13, 1912.)

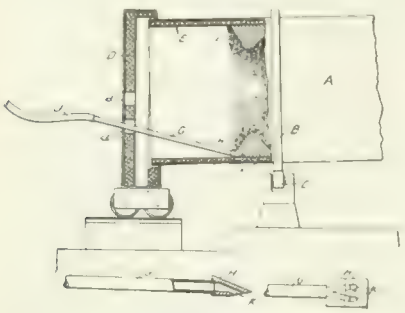

FIG. 1.—DISINTEGRATING NODULIZER KILN RINGS.

Improved Channel Furnace.—An invention relating to furnaces of the Grondal type is illustrated in Figs. 2 and 3, being part of a patent granted to Mr. JOHN W. H. HAMILTON, of St. George, N. Y., and assigned to the American Grondal Company, of New York City. It relates to the construction of the cooling chamber and preheating air passage above the same and to a novel sealing means for maintaining the space above the trucks separated from the air space below them.

In channel furnaces of the Grondal type, it is common practice to preheat the air for the burners by passing it through a passage above the crown of the cooling chamber. Additional heat is extracted from the glowing briquets by passing a stream

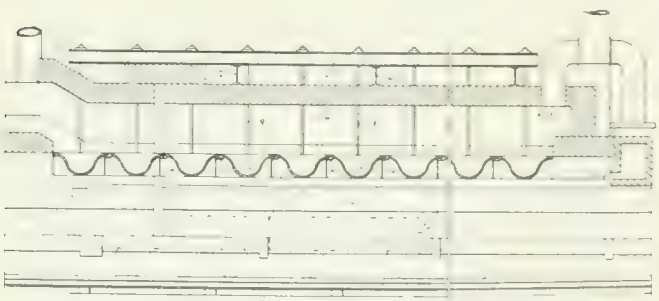

FIG. 2.—IMPROVED CHANNEL FURNACE.

of air over them. Fig. 2 shows a longitudinal vertical section of the improved furnace and Fig. 3 gives a detail of the construction of the crown of the cooling chamber. Instead of the usual crown arch of brick between the side walls of the furnace, the inventor substitutes a roof of a series of metallic castings of the form shown in Fig. 3. These rest at opposite ends on the sides of the furnace and form an undulating metallic ceiling, shown in dark outline in Fig. 2.

The blast of air that flows from the port 13 directly over the briquets 12 on the truck *E*, enters the recesses of the undulatory surface and is deflected down on the briquets. In this manner the air is more highly preheated and the briquets more thoroughly cooled than formerly. Likewise the blast of air entering at the port 15, passing above the roof plates 10, is confined by the roof arch 16 and spreads over the hot roof plates, absorbing a great amount of heat and reaching the burners at a higher temperature than has been attained in former construction.

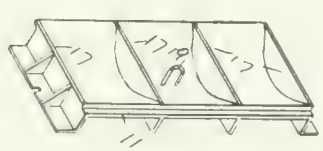

FIG. 3.—DETAIL OF ROOF, CONSTRUCTION OF CHANNEL FURNACE.

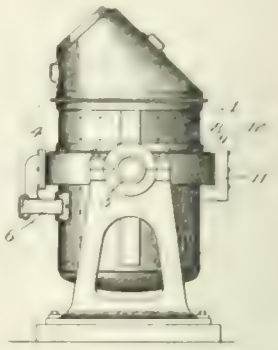
The roof plates 10 are strengthened by longitudinal ribs 17 and are supported also by rods which are hooked into the eyes 19, and attached to the beam 20.

In order to seal the spaces above and below the trucks, the latter are provided with side fins which dip into continuous water troughs extending along the sides of the channel. To obviate the necessity for valve devices at opposite ends of the troughs to permit the entrance and exit of the fins, the track on which the truck runs is inclined slightly at each end of the furnace, so that the fins just dip into the troughs at the ends of the furnace, and are at their deepest point during the travel of the truck through the combustion chamber where the need of the seal is greatest. (1,035,699. Aug. 13, 1912.)

Converter Construction.—Converters usually are constructed with the body or shell permanently secured to the air-box and trunnions, so that the latter parts have to be removed with the shell when it is out of service for relining or any other purpose. A new method of construction patented by Mr. ALEXANDER ZENZES, of Berlin, Germany, and assigned to the Zenzes Converter Company, of Chicago, provides a shell which is detachable from the air-box and trunnions so that the latter may remain in service when the shell has to be removed.



CONSTRUCTION.

By reference to the drawings, Figs. 4 and 5, it will be seen that the shell is constructed in the usual manner, but is supported on the air-box 4 by an encircling angle-iron 8. The air-box and trunnions are pivoted on supports 3. When the shell is placed in position, resting on the air-box, a downward extension of the latter, 6, forms a passage between the air-box and the tuyeres 7, and the several openings are designed to register perfectly and prevent the escape of air. A cover 11 is provided at the right-hand side of the air-box, and being of heavy construction it serves also as a counterweight for the shell. By this construction a damaged shell may be removed from the air-box and trunnions and its place taken by another, so that no time need be lost during the repair of the first shell. (1,035,295. Aug. 13, 1912.)

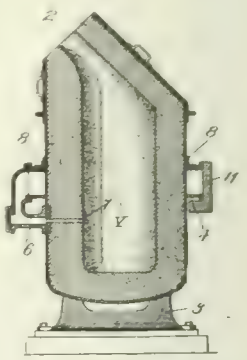


FIG. 5.—IMPROVED CONVERTER CONSTRUCTION.

Gold and Silver.

Electrolytic Amalgamation.—Numerous proposals have been made for the recovery of free gold by amalgamation aided by electrolysis. Two forms of apparatus have been devised namely, the ordinary plate and the mercury riffle or well. For certain reasons the former type has not been successful when the plate is connected as cathode of an electrolytic apparatus, but the latter type has given promise of success. Dr. HENRY NOEL POTTER, of Hollywood, Cal., has devised an interesting apparatus of the riffle or well type, shown in Fig. 6, which may be used either for ordinary amalgamation or in combination with an electric current. The construction of the apparatus embodies several features essential to successful amalgamation.

The apparatus consists of a vertical series of pans 1, which are molded of some insulating composition, preferably Bakelite. Each pan is adapted to hold mercury 3, and there is a passage 4 in free communication with the next lower pan. Above the mercury and so disposed as to provide a definite path for the flowing liquid, is a baffle 8, which also serves as the anode of the apparatus when used electrolytically. The cathode connections to the mercury are made through bars 9.

In operation, the stream of gold-bearing ore flows in a tortuous path through the apparatus from top to bottom, passing

over the baths of mercury and being continuously agitated by the several changes of direction, so as to present new surfaces of ore to the amalgamating bath. The inventor has observed that when a gold-bearing stream flows over a surface of electropositive mercury or amalgam, the extraction seems to be limited to the gold in a thin layer at the bottom of the stream. Hence, the logical manner of improving the extraction lies in periodically mixing the stream and presenting new surfaces to the mercury

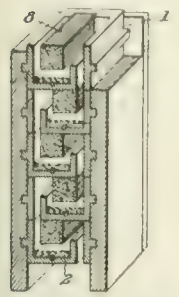

FIG. 6. ELECTROLYTIC AMALGAMATOR

The apparatus may be used without the electric attachments, but where the gold is "rusty," or the mercury tends to become foul, or where native platinum or platinum metals are present, the eletrolytic effects are necessary for best results.

The principle may be applied for the electrolytic decomposition of cyanide solutions of gold and silver. In such a case it would not be necessary to remove suspended solids by filtration. The apparatus may be used also for preliminary treatment of gold-bearing ore to remove the coarse gold by amalgamation and allow the fine metal to be dissolved by a cyanide solution. (1,030,490, June 25, 1912.)

Vacuum Filters.

New adaptations of the principle of the vacuum filter are being proposed by several metallurgists. Recently these are taking the form of groups of filter-leaves mounted vertically about a central shaft and adapted to revolve through a tank of ore-pulp. In our last issue we described one such filter and herewith two more. The first is by Mr. C. K. BARNES, of Pearce, Ariz., and is illustrated in Figs. 7 and 8, the latter showing one of the segmental units of the former. Each segment is a filter on which a cake is formed, washed and discharged during a cycle of operation. By suitable valves and connections, the segment is first acted upon by a vacuum pump and then by compressed air, respectively to form and discharge the cake. The valuable solution is collected through the central shaft.

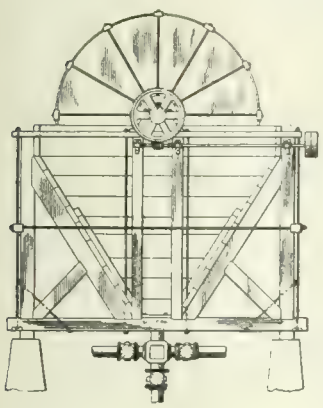

FIG. 7.—VACUUM FILTER.

In operation the tank is first filled with slime and the leaves pass through it and accumulate a cake. The residual slime is then removed from the tank and replaced by wash solution, through which the leaves again pass. After the wash is complete, the tank is again emptied, whereupon the filter-cake is blown off the leaves into the tank and discharged to waste. Each filter segment is formed of a piece of corrugated wood, over which the filtering medium is stretched. (1,036,174, Aug. 20, 1912.)

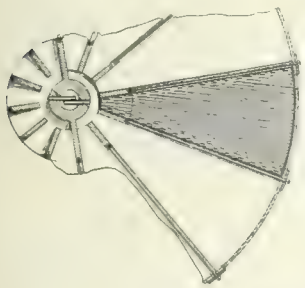

FIG. 8.—SEGMENT OF FILTER WHEEL.

A similar type of filter is shown in Figs. 9 and 10, being the invention of Mr. ARTHUR A. HOLLAND, of Hastings-upon-Hudson, N. Y. This machine differs from the one just described in several particulars. It has a stationary central tube 11, about which the filter-wheels revolve on a sleeve to which they are attached by spokes. The cycle of filtration consists in the formation, washing and discharge of a cake, with separation of the gold-cyanide solution; but the washing is accomplished by sprays of water issuing from wash boxes disposed between the filter-wheels. These are shown in the broken part at 28, with the spray holes at 18. The discharged cake falls from the leaves into a trough 14

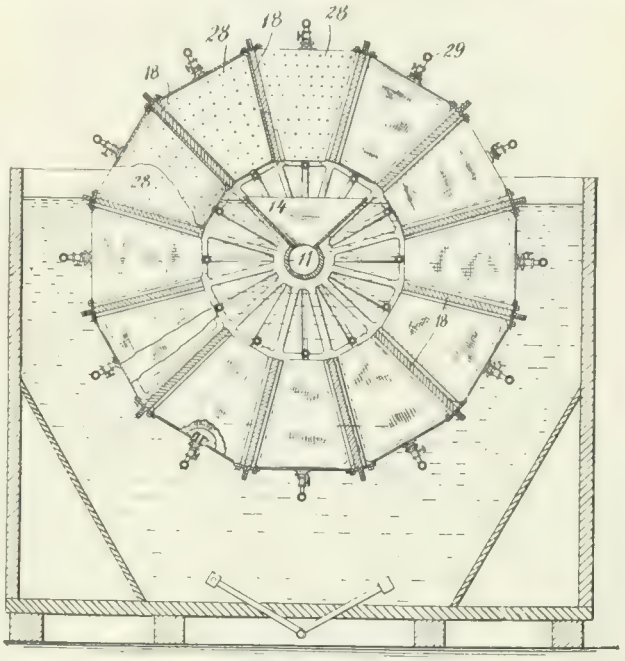

FIG. 9.—REVOLVING VACUUM FILTER.

which is attached to the stationary central tube. The accumulated slime is washed out through this central tube. The gold-cyanide solution is drawn off through pipes 29 which are connected with each series of segmental units, and which have

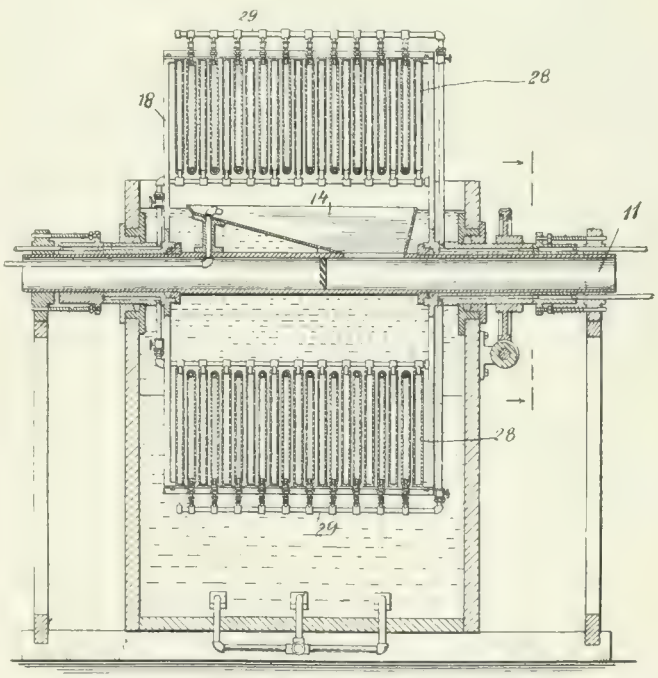

FIG. 10.—REVOLVING VACUUM FILTER.

an outlet through the sleeve about one end of the stationary central tube. Fig. 10 gives a sectional view of the machine. (1,036,847, Aug. 27, 1912.)

Filter Feed.—In Fig. 11 is shown a feed box adapted to deliver slime onto a filter of the type employing a plurality of moving filter pans. It is the invention of Mr. BRUCE W. TRAYLOR, of New York City, and consists of a pipe 2 which deliv-

ers slime into a box 3 which has a series of outlets 3a along each edge. The box is supported as shown at 4. Projections are provided at 5. As the train of pans travels under the feed

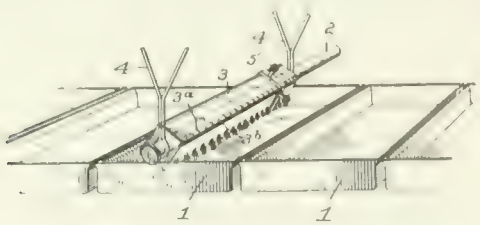

FIG. 11.—FEED FOR PAN FILTER.

box, the pan walls engage the projections 5 and cause the feed box to rotate a quarter-turn, temporarily shutting off the feed so that no slime will be lost, and allowing it to come on again when the next pan is in position. (1,037,561, Sept. 3, 1912.)

Copper.

Combination Smelting Process.—In a patent granted to Mr. Story B. Ladd, of Washington, D. C., he proposes to utilize electric heat to assist in maintaining the proper temperature of the furnace in smelting sulphide ores. The furnace is constructed in the ordinary manner, with the addition of electrodes placed in the hearth. The patentee claims that this method of securing heat will permit the use of only such carbon in the form of coke as may be necessary for chemical action; that the character of the resulting matte will be improved; that it provides a zone of highest heat at the base of the stack below the tuyeres, and that the temperature of the furnace is under more perfect control. (1,035,608, Aug. 13, 1912.)

Separating Solids from Gases.

Electric Precipitation.—It is well known that particles in a gaseous body tend to deposit therefrom when the gas is brought into an electric field between two electrodes of high potential difference. Dr. F. G. Cottrell and Mr. H. A. Burns, the former of Berkeley, and the latter of Oakland, Cal., make use of this principle in a patented process for separating suspended particles from gaseous bodies.

The deposition of such suspended particles is facilitated if the terminals of the electric field, in which the gas is inclosed, are of the nature of sharp points or edges, fine hairs or similar bodies of very small electric discharge surface. Such bodies are used as "discharge" electrodes, in contradistinction to "collecting" electrodes, the latter being relatively large in area and of smooth surface. Suspended particles in gases under treatment tend to deposit mainly on the smooth electrodes.

The selection of suitable "discharge" electrodes has been one difficulty encountered in applying the process on a commercial scale. Further difficulties have been found in suitably arranging and suspending the electrodes in flues or chambers so as to secure rapid precipitation. It is the object of the improvements described here to meet these difficult conditions. Discharge electrodes must resist deteriorating action of the gas and should present the greatest number possible of fine points or edges. Further, the material should be sufficiently non-inflammable and heat resisting so that no damage will be done by occasional arcing. Sheet mica in some form has been found eminently satisfactory for the purpose. In order to provide conductance the mica is clamped between supporting structures which are electrical conductors, and this is done in such a manner that the relatively narrow protruding, serrated edges of mica may be sufficiently charged through surface leakage from the charges imposed on the supporting structure.

Fig. 12 gives a view showing the manner of assembling the discharge and collecting electrodes, with features of support and insulation. This system is called by the inventors the "staggered" arrangement. The collecting electrodes *A* are suspended parallel to the direction of flow of the gas from supports 5. Swinging of the plates is prevented by a guide 6. Where the collecting electrodes are to be grounded, the discharge electrodes must be insulated and maintained at a fixed distance from the opposed collecting electrode. The supports must be provided outside the flue where the insulation can be kept clean and dry. Thus, busbars 8 resting on insulators 9 must pass through sufficiently large holes in the walls of the flue so that there will be no arcing at this point. The discharge electrode *B* is keyed to the top of busbars 12. The latter are, in turn, supported by bars 13 running parallel with the flue walls and held on horizontal bars 8 resting on the insulators 9, which are outside the flue

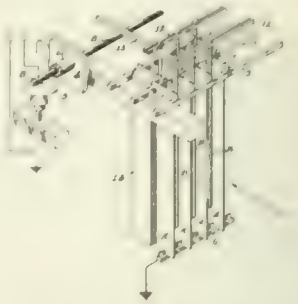

FIG. 12.—ELECTRIC PRECIPITATION OF SUSPENDED PARTICLES.

(1,035,422, Aug. 13, 1912.)

The Vaporization of Metals.*

By Prof. Joseph W. Richards.

Most practical metal workers know that some metals are volatile. No one knows many exact facts about this matter.

Metals have vapor-tension curves similar to that of water. Water at ordinary atmospheric pressure boils at 100 deg. C., or 212 deg. F. But at lower pressures it boils at lower temperatures; at half atmospheric pressure it boils at one-tenth atmospheric pressure at 46 deg. C., and at one-hundredth atmospheric pressure at 7 deg. C.

A point not generally understood, is that an indifferent gas in contact with a volatile substance acts like a vacuum as far as inducing evaporation is concerned. Water evaporates in a current of dry air at any temperature whatever; the only condition being that the dry air be renewed as fast as it becomes saturated with the water vapor. Even solid water, ice, will evaporate in a current of dry air, although the temperature remains below the melting point of the ice.

All that has been said of water is true of metals. They all have definite boiling points under atmospheric pressure, lower boiling points at lower pressures, and can evaporate at any temperatures down even to their freezing points, if the pressure is sufficiently reduced. They will also vaporize at low temperatures in the presence of an indifferent gas, if the latter is renewed as fast as it is saturated with the metal vapor.

To illustrate the above principles, let us cite zinc, which boils under atmospheric pressure at 920 deg. C., but which has an appreciable vapor tension at as low a temperature as 289 deg. C. or 130 deg. C. below its melting point. This tells us that not only will zinc evaporate rapidly when melted, in a current of indifferent gas, but that even solid zinc can give off zinc vapor. Similar facts are true, although in a smaller degree, of many metals ordinarily considered as non-volatile. Silver, for instance, can evaporate from solid ingots which are being heated by direct contact with a flame, the gases of the flame carrying away with them more or less silver vapor, just as dry air can carry off water vapor from ice.

Evaporation and volatilization of metals can best be avoided by melting them out of contact with currents of gases; that is, by heating in closed vessels. This can be accomplished either by melting them in crucibles with covers, or by using electric furnace heating. The latter is to be preferred, and will be found much less expensive for power than is commonly supposed. I believe, for instance, that brass can be, at the present time, melted more cheaply in electric furnaces than by fuel, almost anywhere in the United States, with great saving of the zinc usually vaporized.

*Abstract of a paper read at the Allied Foundrymen's Convention in Buffalo, last month.

Synopsis of Chemical and Metallurgical Literature

Heat Transmission of Vacuum Evaporator Tubes.—Prof. H. McCORMACK has carried out a joint investigation with Messrs H. C. DORMITZER and P. ROLESON on the comparative efficiency of copper, steel, lead, and tin for vacuum evaporator tubes. The tests were made with a Swenson evaporator. The results of the tests are given in form of tables in the July issue of *Chem. Eng.*

The average results of this series of tests may be summed up as follows: Copper tubes, efficiency 83.4 per cent; steel tubes, efficiency 79.5 per cent; tin tubes, efficiency 76.7 per cent, and lead tubes, efficiency 78.8 per cent.

From the above results it may be seen that the efficiency is highest for the copper tubes and next highest for the steel tubes. These results would be expected, inasmuch as copper and steel have a higher coefficient of heat transmission than the other materials used, and also from the fact that the copper and steel tubes were from one-third to one-fourth as thick as the other two sets of tubes. The difference in the efficiency of the copper and of the steel is not as great as might be expected from the difference in their heat conductivities. This is, doubtless, due to the fact that both tubes were very thin.

The relation of the efficiencies of the lead and tin tubes are somewhat harder to explain. Although the coefficient of heat transmission for tin is greater than that of lead, and although the lead tubes were about one-eighth thicker, the efficiency of the latter is greater. It may also be noted in this connection that the exhaust steam came out at a lower temperature in the case of the lead tubes, than of the tin. Unless there is some unknown error in these determinations the authors are unable to account for these facts.

In general it may be said that there is very little difference in the efficiencies for the various tubes, the maximum difference being 6.7 per cent. This is doubtless due to the fact that, with tubes of the small thickness used the coefficient of heat transmission does not materially affect the efficiency. This figure may be altered one way or the other, by changing the velocity of the steam.

Coking of Coal at Low Temperatures.—Bulletin No. 60 of the University of Illinois, Engineering Experiment Station, contains a paper on the coking of coal at low temperatures, with a preliminary study of the by-products, by Prof. **S. W. Parr** and **Dr. H. L. Olin.** The seven chapters deal with introduction, experimental work, gases, tar, coke, the formation of coke, and summary. The conclusions of the authors are as follows:

1. Coals of the Illinois type can be coked at a temperature approximately 400 deg. or 450 deg. C.

2. The gaseous products consist chiefly of illuminants of high candle-power, and represent, together with the condensible material under (3) following, the chief elements involved in formation of smoke in the ordinary combustion of raw coal. The nitrogen of the coal is liberated as NH_3, at these temperatures, in amounts representing approximately 20 per cent of the total nitrogen present.

3. The condensible distillate consists largely of oils with the minimum amount of tar and free carbon. The oils represent positive values for fuel, for carburetting water gas, or for other specific uses, on account of their chemical characteristics as unsaturated compounds.

4. The coke residue has special characteristics which seem to make it of value as a concentrated fuel, capable of combustion without the formation of smoke, suitable for storing without the possibility of spontaneous combustion, and presumably adapted to the manufacture of gas for use in the suction gas producer.

5. Certain facts seem to have been developed concerning the principles involved in the formation of coke which may open the way to the production of a kind of coke of such texture and strength as to make it acceptable for uses that are not now possible with coke made from similar coal, but formed under ordinary conditions, such as are found in the ordinary gas house retort practice, or that of the by-product coke oven.

Other considerations are pertinent in this connection, such as losses and pollution of the atmosphere which accompany the production of smoke.

Further studies have in mind the carrying out of the processes as indicated with apparatus involving the continuous feature, subjecting the mass at the point of greatest fusibility to the pressure of the oncoming material and producing the coke in amount sufficient for testing its properties in the gas producer and for combustion in other ways which would test its properties as a smokeless fuel.

There is an appendix giving a review of the literature on low-temperature distillation including the studies of the by-products, followed by references to the theories concerning coke formation and the carbonization of coal in general.

Alumina as Drying Agent.—In the July issue of the *Journal* of the American Chemical Society appears a note by F. M. G. JOHNSON, of McGill University. The results recorded are so striking that they would seem to suggest technical applications, though this is not mentioned. "In the course of an investigation on phosphonium compounds a drying agent was necessary which would successfully dry both PH_3 and HI or HBr, since P_2O_5 proved useless for this purpose. Satisfactory results were obtained by employing Al_2O_3 prepared by igniting the hydroxide at a low temperature. A test of the efficiency of this substance to take up moisture was made by passing air saturated with water vapor at room temperature, about 18 deg. C., through a tube containing about 7 gr. of the oxide, and then through a second tube filled with P_2O_5. The air was led through at the rate of about two or three bubbles per second. Both tubes were weighed from time to time.

"The somewhat remarkable result obtained was that the P_2O_5 tube showed no perceptible gain until the Al_2O_3 had increased about 18 per cent in weight, corresponding to the formation of the hydrate $Al_2O_3.H_2O$. The reaction is generally represented by the equation $Al_2O_3 . 2AlO(OH)$.

"The formation of the hydrate is accompanied by evolution of heat, hence increased temperature causes its dissociation into Al_2O_3 and H_2O. It is thus seen that 1 gr. of Al_2O_3 can practically completely absorb all moisture from approximately 10 liters of air saturated with water vapor at 180 C.

"G. P. Baxter and R. D. Warren investigated the drying properties of $CaBr_2$, $ZnBr_2$, and $ZnCl_2$, and from their results it is seen that compared with Al_2O_3 these substances are much inferior as desiccating agents. Al_2O_3 is also more effective than H_2SO_4. A tube filled with Al_2O_3 can be used for an indefinite period, if from time to time it is heated with a smoky flame while air, previously led through H_2SO_4, is passed through it. To replace the usual P_2O_5 tube used in connection with mercury pumps it appears particularly suitable, since the tube used need never be renewed. A small tube of P_2O_5 following the Al_2O_3 would serve to indicate when the Al_2O_3 needed reheating. Its uses in many investigations are obvious."

Heating of Nitro-glycerine.—Technical paper 12 of the Bureau of Mines, deals with the behavior of nitro-glycerine when heated, the authors being WALTER O. SNELLING and C. G. STORM. Nitro-glycerine begins to decompose at temperatures as low as 50 deg. or 60 deg. C. At a temperature of 70 deg. C. nitro-glycerine of commercial quality evolves enough nitrous fumes to give a decided test with potassium-iodide-starch paper at the expiration of 15 to 30 minutes. Moreover, nitro-glycerine tends, even at very low temperatures, to be somewhat volatile, and it is well known that even at ordinary room temperatures nitro-glycerine loses slowly in weight through volatilization. At somewhat higher temperatures both the decomposition and the evaporation of nitro-glycerine increase. At a temperature of

about 135 deg. C. the decomposition of nitro-glycerine is so rapid as to cause the liquid to become of a strongly reddish color, owing to the absorption of the nitrous fumes resulting from that which is decomposed; and at a temperature of about 145 deg. C. the evolution of decomposition products is so rapid that, at atmospheric pressures, ebullition begins, and the liquid "boils" strongly. This "boiling" is due in part to the evolution of decomposition products (mainly oxides of nitrogen and water vapor) and in part to the actual volatilization of nitro-glycerine itself.

The decomposition of nitro-glycerine is accompanied by the evolution of much heat, and as soon as ebullition of a sample of nitro-glycerine has begun, enough heat is generated within the liquid to rapidly raise the temperature of the mass, unless some means is provided for conducting away the heat evolved. At temperatures between 145 deg. and 215 deg. C. the ebullition of nitro-glycerine becomes more and more violent; at higher temperatures the amount of heat produced by the decomposing liquid becomes proportionally greater, and at about 218 deg. C. nitro-glycerine explodes.

When nitro-glycerine is maintained at a temperature between 145 deg. and 210 deg. C., its decomposition goes on rapidly, accompanied by much volatilization, and under these conditions nitro-glycerine may be readily distilled. The distillate consists of nitro-glycerine, nitric acid, water, and other decomposition products. The residue that remains after heating nitro-glycerine under such conditions for some time probably consists mainly of glycerine, with small amounts of dinitroglycerine, mononitroglycerine, and other decomposition products. These substances are far less explosive than ordinary nitro-glycerine, and accordingly by heating nitro-glycerine slowly it can be caused to "boil" away until the residue consists of products that are practically nonexplosive. In a number of experiments nitro-glycerine was thus heated, and a copious residue was obtained. By carefully raising the temperature this residue could be made to char without explosion.

Electrolytic Copper in Norway.—According to a note in the *London Electrical Review* of October 4 "the past 12 months has witnessed the erection at Aamdal of the first copper works to produce pure copper on the spot where the ore is mined by M. Hybinette's process of extraction, during which the copper is elutriated from the ore by weak sulphuric acid and precipitated from the solution to pure copper by the help of electricity. The works will probably increase their production in the coming year to 3 tons of metallic copper per diem. The satisfactory results at Aamdal, and experiments with the so-called 'kisafbrand,' or pyrites burnings, from the Orkla Mine —one of the largest Norwegian copper and sulphuric mines— have brought into prominence the possibilities of a new Norwegian industry. Owing to the want of suitable Norwegian copper works, the Orkla and Sulitjelma Mines, in both of which foreign capital is largely interested, have hitherto exported their copper sulphur pyrites to Germany and Helsingborg, respectively, to have the copper extracted there. It now, however, appears likely that the Hybinette companies will receive the necessary support from Norwegian cellulose and other manufacturers interested in the consumption of sulphur to enable them to take over this industry." In his paper on the electrochemical industries of Norway (our vol. IX, p. 544, Oct., 1911), Jos. W. Richards mentioned a copper-nickel refinery depending for its ore supply on a copper-nickel mine. The ore is smelted by semipyritic smelting near the mine and the nickel-copper matte shipped to the refinery, where the nickel and copper are electrically separated by the process of Hybinette. The Hybinette separating process was described in our vol. IV, pp. 33 and 34, 1906.

Light Aluminium Alloys.—A paper by Prof. **Ernest Wilson** read before the British Association, noticed in London *Electrician*, Sept. 13, gives the results of exposure tests of light aluminium alloys. Each alloy was suspended on the roof of King's College, London, in order to investigate the influence of exposure upon electrical conductivity. All the specimens are in the form of wire 0.126 in. (3.2 mm.) diameter, and all the resistances are reduced to 15 deg. C. Alloying commercial aluminium with copper alone has proved unsatisfactory, as a 2.6 per cent copper alloy had completely deteriorated in ten years and increased its electrical resistance 25 per cent.

An increase in the percentage of the iron always found in commercial aluminium, or the addition of nickel or manganese to an alloy containing about 0.09 per cent of copper, has beneficial results both from the standpoint of tensile strength and the power to resist deterioration. For example, specimens containing, respectively, 1.16 per cent iron, 2.25 nickel and 1.78 manganese have only increased their electrical resistance about 9 per cent in eleven years.

"Duralumin" is a copper-manganese alloy of aluminium with the addition of about 0.5 per cent magnesium. A specimen about 80 ft. long has been exposed one year and has increased its electrical resistance 5.15 per cent. It would be interesting to know if this is due to the comparatively large percentage of copper (3.5 to 5.5) which this alloy is stated to contain, or if the percentage of manganese (0.5 to 0.8) is too low. This alloy has attracted attention in that a breaking load as high as 90,000 lb. can be obtained, if desired, according to treatment; but as an electrical conductor it does not compare well, since the specific resistance is about twice as great as that of commercial aluminium. A specimen of high-conductivity copper about 80 ft. long has been exposed for one year, and has increased its electrical resistance 1.2 per cent.

The Laws in Force in Europe Against the Emission of Black Smoke

By John B. C. Kershaw.

The increased attention that is now being given on both sides of the Atlantic to the subject of Smoke Abatement, and the success that has attended the efforts of the Public Health Authorities of many important Cities and Centres of manufacturing industry to improve the purity of the atmosphere renders a comparison of the Laws which are in force in different countries, against the pollution of the air by black smoke, of especial interest at the present time.

The American Laws against smoke emission vary greatly in the different States and Cities, as the majority of the readers of this journal are no doubt aware.

The same condition of affairs exists to a lesser extent in Europe. In certain cities and districts the laws against smoke are stringent, and are vigorously enforced, while in others, considerably laxity is shown, and proceedings against manufacturers for excessive smoke emission are rarely indulged in, and, when undertaken, are rarely successful.

But, although the laws relating to excessive smoke emission may be extremely faulty, and although there may be also great laxity with regard to their enforcement in many places, those who are engaged in an earnest attempt to improve the atmosphere of the chief centres of population and industry in this and other countries cannot afford to be entirely ignorant of the legal side of smoke abatement. The writer in the present article will therefore bring under review the legal position in regard to smoke abatement in Great Britain, and some details will be given also of the proposed amendment and consolidation of the English Acts relating to smoke abatement. The state of the law in Paris, Germany and Austria will de dealt with finally very briefly.

Great Britain.

The English Law relating to the emission of smoke from chimneys is complicated by the fact that the provisions of the Public Health Act of 1875, which apply throughout England (with the exception of London) are amplified and extended by the local Acts of the larger and more important municipal-

tities. Procedure against offenders may be taken either, 1, under the Common Law, 2, under the Public Health Act of 1875; or 3, under the Smoke Clauses inserted in these various local Public Health Acts.

As the powers conferred by the latter are not uniform, there is considerable force behind the demands now being raised for a revision and consolidation of the laws relating to smoke, and for the passing of an Act which would apply to the whole country. The difficulty in obtaining convictions for the emission of black smoke at present, however, is due to the reluctance of Magistrates and Stipendiaries to enforce very strictly the existing laws, and it is very doubtful whether a greater number of convictions would be obtained under a uniform and more stringent law, applicable to all districts of the country. In the writer's opinion, further education of public and private opinion in the scientific principles of smoke abatement is required before more stringent legislation on the subject can be effective. He believes therefore that the efforts now being made to draft and pass a new Bill, through the present Parliament, will prove abortive.

The emission of smoke is held to be a nuisance under *Common Law* when it can be proved that injury to health, to public or private property, or personal discomfort, has resulted from the same. Although convictions have occasionally been obtained under this law, it is not usually invoked in smoke nuisance procedure, since the clear proof required that the injury is due *alone to smoke*, and also to the smoke emitted by *one particular chimney*, is not easily given.

Clauses 91-98 of the Public Health Act of 1875 contain the statutory law relating to the emission of smoke throughout England, and it is under these clauses, or under similar provisions in the various local acts, that offenders are generally proceeded against when a nuisance has occurred.

Section 91, Sub-sections 7 and 8 of the 1875 Act are the most important, and enact that (7) "Any fireplace or furnace which does not, as far as practicable, consume the smoke arising from the combustible used therein, and which is used for working engines by steam, or in any mill, factory, dyehouse, brewery, bakehouse, or gasworks, or in any manufacturing or trade process whatsoever"; and (8) "any chimney (not being the chimney of a private dwelling-house) sending forth black smoke in such quantity as to be a nuisance shall be deemed to be a nuisance liable to be dealt with summarily in manner provided by this Act. Provided,"

First . . .

Secondly: "That where a person is summoned before any Court in respect of a nuisance arising from a fireplace or furnace which does not consume the smoke arising from the combustible used in such fireplace or furnace, the Court shall hold that no nuisance is created within the meaning of this act, and dismiss the complaint, if it is satisfied that such fireplace or furnace is constructed in such manner as to consume as far as practicable (having regard to the nature of the manufacture or trade) all smoke arising therefrom, and that such fireplace or furnace has been carefully attended to by the person having charge thereof."

The remaining Sections of this Act (92-98) deal with the methods by which the law is to be set in motion, this duty being cast upon the Local Authorities, and if they do not act, upon the Local Government Board. One of the present grievances of Smoke Abatement Reformers in England is that the Local Government Board rarely exercises its authority under this Act, and that it allows certain Local Authorities (notably that of West Ham) to neglect its duties with impunity in this matter of smoke emission. The explanation is that West Ham is the most heavily rated District of London, and that to enforce within this District the Smoke Nuisance Clauses of the Public Health Act of 1875 more strictly would involve driving large numbers of manufacturers away from the District, and increasing the burden of the rates upon those that remained.

The Public Health (London) Act of 1891 applies to the Metropolis within the area covered by the administrative County of London, and contains Clauses (23-24) relating to the emission of Smoke, based on those of the Public Health Act of 1875. Clause 23, Sub-section 2, of the London Act, is, however, more stringent than Clause 91 of the 1875 Act, for it imposes cumulative fines for every successive conviction on any person who "being the owner or occupier of the premises, or being a foreman or other person employed by such owner or occupier, (a) uses any furnace 'employed in trade' which is not constructed so as to consume or burn the smoke arising therefrom, or (b) so negligently uses any such furnace so that the smoke therefrom is not effectually consumed or burnt, or (c) carries on any trade or business which occasions any noxious or offensive effluvia, or otherwise annoys the neighbourhood or inhabitants, without using the best practicable means for preventing or counteracting such effluvia or other annoyance."

Clause 24 of the London Act is similar in scope and application to Sub-section 8 of the 1875 Act, and enacts that—

"Any chimney (not being the chimney of a private dwelling-house (sending forth black smoke in such quantity as to be a nuisance shall be a nuisance liable to be dealt with summarily under this Act."

By a decision of the courts given in 1903, it was held that Club premises in London could not be regarded as a "private dwelling-house," and that the owners of these could be proceeded against under the Act for nuisance arising from the emission of smoke. The most notable decision under this Act, however, has been that delivered by Mr. Curtis Bennett, in the prosecution of the owners of the large electrical generating station, situated in Lots Road, Chelsea, which supplies power for the London underground railways. This station possesses four chimneys, each 19 feet in diameter at the top, and the defence was, that the smoke only appeared "black" on account of its great depth and volume, and that if it had issued from a larger number of chimneys of smaller diameter, it would have escaped the notice of the Smoke Inspector. Mr. Bennett on the ground of this specious defence gave a decision in favor of the defendants, and since that date it has been much more difficult to secure the punishment of offenders, for nuisance arising from smoke, within the metropolitan area. The attempt made by the London County Council in April, 1910, to obtain an amendment of the law by deletion of the word "black" from Clause 24 of the Act of 1891 failed, and the legal position as regards smoke emission within the Metropolis is therefore left in the somewhat unsatisfactory state to which it has been reduced by Mr. Curtis Bennett's decision of 1908.

Local Acts.

The Municipality of Glasgow have been the most active and successful in regard to the subject of smoke abatement. Proceedings for nuisance arising from smoke in that city are taken under Section XXXI of the Glasgow Police Act of 1892, which reads as follows:

"Every person who so uses, causes, permits, or suffers to be used, any furnace or fire within the City (except a household fire) so that smoke issues therefrom, unless he proves that he has used the best practicable means for preventing smoke, and carefully attended to, and managed such furnace or fire as to prevent as far as possible smoke issuing therefrom, shall be liable for the first offence to a penalty not exceeding forty shillings, and for the second or any subsequent offence (if committed within twelve months of the immediately previous conviction) to a penalty not exceeding five pounds."

The Municipality of Glasgow maintains five Smoke Inspectors to enforce the provisions of this Act.

Manchester.

Although Manchester possesses a Local Act of 1844 that contains a clause dealing with smoke emission, proceedings in

that City are always taken under the smoke clauses of the Public Health Act of 1875. The penalty that can be imposed under this Act has, however, been increased to £10, and the aggregate time allowance for black smoke is two minutes in an observation extending over thirty minutes. The City maintains four Smoke Inspectors.

Liverpool.

Proceedings in Liverpool are generally taken under Section 24 of the Sanitary Amendment Act passed in 1854, as amplified by the later extensions (obtained in 1882, 1902 and 1905) bringing within the scope of the Act steamboats plying for hire in the River Mersey, and all furnaces employed for any purpose in the City other than (a) domestic fireplaces, and (b) furnaces employed in working the engines of any vessel not already subject to the provisions of the said Section.

Section 24 of the 1854 Act is worded as follows:

"And whereas it is expedient to make further provisions for the prevention of nuisances arising from the emission of smoke: Be it enacted that all furnaces employed in the working of engines by steam, and all furnaces employed, or to be employed, in any mill, factory, forge, foundry, sugar-refinery, pottery, distillery, chemical works, dyehouse, brewery, bakehouse, gasworks, waterworks, and other buildings used for the purpose of any trade or manufacture whatsoever, within the said borough (whether a steam-engine be used or employed therein or not); and all furnaces employed in working the engines of any steamboat plying on the River Mersey, and of any steam-tug or boat employed for the purpose of towing or hauling any ship or vessel in the said River, or plying for such employment, shall in all cases be constructed or altered so as to consume or burn the smoke arising from such furnace; and if any person shall use any such furnace which shall not be constructed to burn or consume its own smoke, or shall so negligently use any such furnace so that the smoke arising therefrom shall not be effectually consumed or burnt, or so that an unnecessary or excessive quantity of smoke shall be emitted, or shall carry on any trade or business which shall occasion any noxious effluvia or otherwise annoy the neighbourhood or inhabitants, without using the best practicable means for preventing or counteracting such smoke, or other annoyance, every person so offending, and the owner or occupier of the furnace from which such smoke is emitted, or of the place where such trade or business is carried on, and the owner, master, or other person in command or charge of such steam-boat, shall forfeit and pay a sum of not more than £5 for and in respect of every day during which, or any part of which, such furnace or annoyance shall be so used or continued. Provided always that the words 'consume or burn the smoke' shall not be held in all cases to mean 'consume or burn all the smoke,' and the Justice before whom any person shall be summoned may remit the penalties enacted by this Act if he, or they, shall be of opinion that such person has so constructed or altered his furnace as to consume or burn, as far as possible, all the smoke arising from such furnace, and has carefully attended to the same, and consumed or burned as far as possible the smoke arising from such furnace. Provided also, that no proceedings shall be taken under the above Section except by some Officer of the Council, duly authorized by the Health Committee in that behalf.

The latter part of this Clause considerably weakens the first portion, and leaves rather too much latitude in the hands of the Justices. Liverpool maintains three Smoke Inspectors.

Proposed Amendment of the Law.

The main provisions of the general and local acts relating to Smoke Abatement in Great Britain have been dealt with briefly in the preceding portion of this article. It will now be useful to glance at the main provisions of the Amended Act which is being prepared for presentation to Parliament this year by those who desire to see the existing powers of the Local Authorities in relation to this subject strengthened and made more uniform. The chief objects of those who are promoting this measure are: (1) to obtain one uniform law for the whole country, thus avoiding the difficulty that now confronts the local authority of West Ham; (2) to remove the Smoke Inspectors and others who have to administer the Act from complete dependence upon the local authority for their position, influence and income; (3) to increase the minimum fine for offences under the Act, and to make such fines cumulative in effect for repeated offences.

Local Smoke Prevention Authorities would be constituted by order of the Local Government Board to enforce the provision of the Act, and these bodies would appoint Local Smoke Inspectors who would be paid, as to one-half of their salary by the Local Authority, and as to the other half by the Local Government Board. Government Smoke Inspectors would be appointed also by the latter, each to have charge of certain districts (as under the Alkali Acts), in order to ensure that no Local Authority was neglecting its duties in relation to the proper enforcement of the Act.

That an Amended Act on these lines will be passed for England sooner or later the writer fully believes; the experience gained under the Alkali Acts showing the value of properly trained and qualified Inspectors in aiding the manufacturers to conduct their works without the creation of any nuisance. It may be doubted, however, whether public opinion is yet sufficiently educated to supply the force necessary for driving a Smoke Abatement Act through Parliament; and if it were, the present British Government has its time too fully mortgaged to allow it to take up a measure of this kind unless assured that it would be treated as a non-controversial Bill.

France.

There is no legislative enactment in France for the prevention of the emission of smoke from factories or business premises, but a series of ordinances have been published in Paris by M. Lepine, the energetic Chief of the Police. This City, which is generally regarded as the cleanest city in Europe, is under a law which is much more lax than that enforced in London.

The prefect of police published an ordinance on the 22nd of June, 1898, prohibiting the prolonged emission of thick black smoke from industrial establishments. Six months were allowed to manufacturers to carry out the necessary improvements, but the prefect of police has refrained from a rigorous application of the regulations owing to the impossibility of finding an absolutely perfect apparatus for consuming smoke. Choice of fuel, care in stoking furnaces, and well-constructed chimneys may contribute largely to the restriction of smoke, but cannot entirely prevent its emission.

After stoking furnaces every morning, and after each successive stoking during the course of the day, the Inspector allows an emission of smoke three times as long as that allowed in London, under the law of the 5th August, 1891. Great difficulties were met with by the Paris Municipality in carrying out the regulations, owing to the bad examples set by many public buildings, the managers of these refusing to comply with the provisions of the Decree of 1898.

The cleanness of Parisian buildings and clearness of Parisian skies is therefore more due to the absence of the open fireplace from the domestic hearth than to the strictness of the laws against the emission of black smoke.

Germany.

Mr. Arnold Robertson, Third Secretary of the Embassy at Berlin, states in his Report that there are no actual laws in force in Germany for the restriction of the emission of smoke from factories, business premises, and private dwelling-houses. Although no laws are in force, however, great attention has been given to the subject by the State Authorities, and a commission was appointed a few years ago to examine and report upon the means generally adopted for smoke prevention or

consumption. As a result of the labors of this commission, a circular letter was sent by the Prussian Department for Trade and Industry to the various local authorities, requesting them to see that the measures recommended by the commissioners were adopted in all works and factories belonging to the State, or under State control. For guidance in this matter the Department also published a leaflet of instructions to the local authorities, embodying the more practical portion of the principles and teachings of the commissioners. The educational value of the examples set by the factories and works owned by the State Authorities was therefore expected to minimize the smoke evil in Germany.

Austria.

Many complaints have recently been made in Austria with regard to the emission of thick black smoke from factories and furnaces in the various parts of the country. This has been specially the case in industrial centres, where there is great consumption of coal and other kinds of fuel, and in the various health resorts and watering places, where it is of special importance that the air should be kept pure and uncontaminated by smoke. This problem also presents itself in the case of railways, where the interests of the travelers and those of residents in the neighborhood of stations come into consideration. That no legislative measures exist at present to obviate this nuisance may be attributed to the following causes:

In the first place it must be emphasized that the compulsory introduction of technical measures to procure smokeless or almost smokeless fires would only be practicable if thoroughly adequate appliances existed to ensure the desired result. In this connection experience shows that no system hitherto recommended and applied is exempt from serious disadvantages. The best laid furnace requires constant supervision and attention, nor will it burn properly unless carefully tended. *There is a well-known saying to the effect that a good stoker is the best consumer of smoke.* It must also be taken into consideration that manufacturers oppose a justifiable resistance to the introduction of more or less expensive apparatus for the prevention of smoke, on the ground that the saving of fuel alleged by the inventors does not in reality take place.

In spite of these various difficulties, the problem of finding the best means of combating the smoke nuisance has never been lost sight of in Austria, and it is at the present moment forming the subject of negotiations between the competent Government Departments.

The above extracts are taken from a Government Report relating to the *"Laws in force in certain Foreign Countries in regard to the Emission of Smoke from Chimneys,"* published by the British Foreign Office, in February, 1905.

They indicate that on the Continent of Europe the authorities believe more in educational than repressive measures for dealing with the smoke nuisance, and emphasize the author's view that the best work at present is the education of factory owners, boiler engineers and firemen in the scientific principles underlying the combustion of fuel in the furnaces of heating apparatus generally, and more especially in the furnaces of steam-boilers.

London.

Jigging Unsized Ores.

BY EDWARD T. WRIGHT.[1]

Advance in Present-Day Milling Methods.

Under the sizing system of concentration, classification is the bugbear of the mill designer and operator. No part of the mill presents so much detail, all preliminary to the actual work of separating mineral from gangue. The preliminary separation has been elaborated until many of our mills are very complicated, even bewildering. The proper sizes must be determined, and a selection made of the kind of screens to be used; the merits of trommels, impact or vibratory screens, etc., must be considered to suit the service and ore in hand. Sizes such as the following: 1½ in., ⅞ in., ⅜ in., 3/16 in., 3/32 in., and 2½ mm. may be made with screens; then for the finer sizes we have to select hydraulic classifiers with their four to eight classifications, and with their large consumption of water.

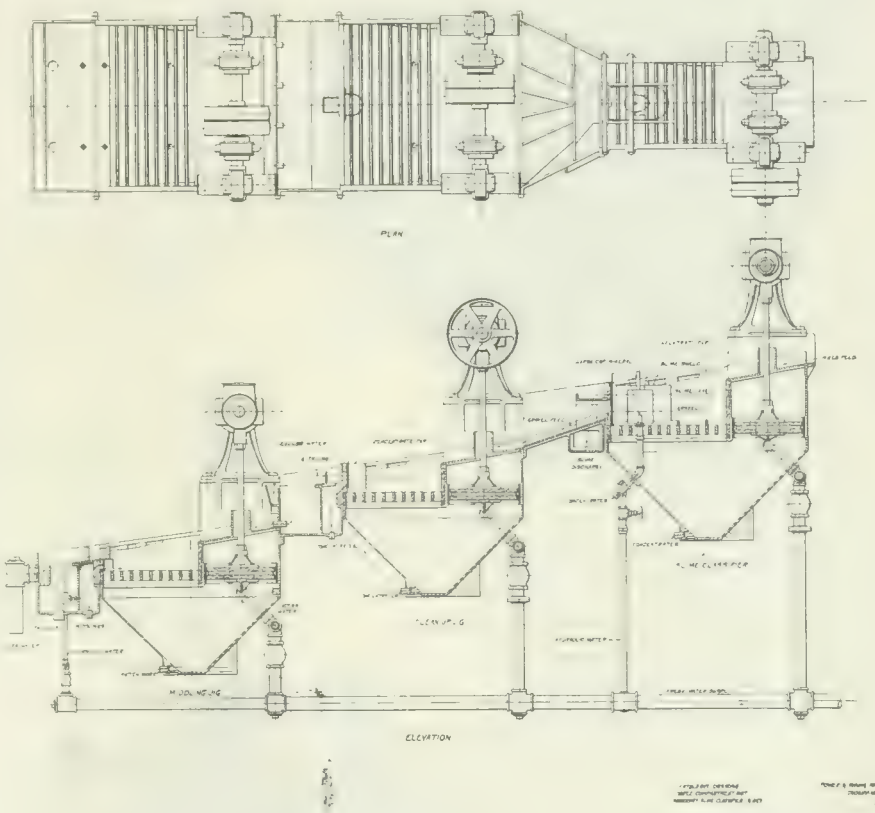

FIG. 1.—THREE COMPARTMENTS UNIT, WOODBURY SLIME CLASSIFIER AND JIGS.

Why all this detail? We understand it is to prepare the ore for the concentrating machines—jigs and tables; that in order to do perfect work these machines must treat nicely sized feeds. Has it ever occurred to us that this preliminary separation may be a result and outgrowth of faulty final separators? That it may not increase our final recovery, but actually lessen it by seriously diluting the ultimate slimes? The hydraulic classifier in making a separation of slime from sand causes a dilution of slime of from 50 per cent to 100 per cent, it being necessary as a result of this dilution to provide elaborate settling systems with resulting overflow losses in fine mineral in order to obtain a slime of proper density for treatment on tables or vanners.

The purpose of this article is to point out to the users of milling machinery a means of simplifying and modernizing the mill, not however, at the expense of recovery of mineral, but actually with largely increased recovery.

Jigs of the Harz type, while they are the oldest of successful

[1]Ore Milling Engineer, Chicago, Illinois.

appliances for jigging ores, do indifferent work on mixed or unsized feeds, and the sizing system has been built up around and to conform with them. We will consider, therefore, a means whereby the complications of the sizing or preliminary

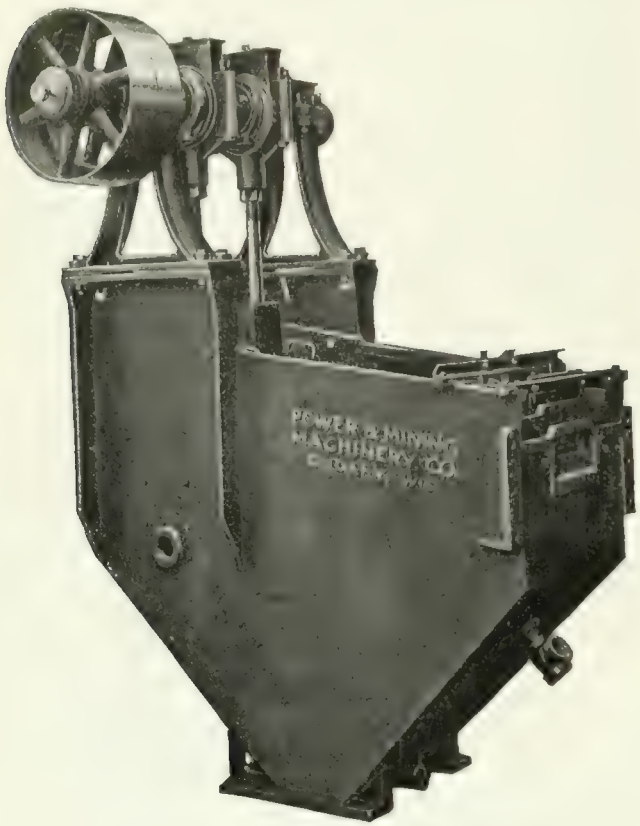

FIG. 2.—SLIME CLASSIFIER, CAPACITY 250 TONS.

treatment can be almost entirely eliminated, while at the same time the slimes are separatd with little or no dilution.

The Ideal Concentrator.

An ideal concentration would be one that would effect a perfect separation of all free mineral and middling from an absolutely mixed or unsized feed, including gravel, sand and slime. As a matter of fact, an unsized feed when passing over a suitable jigging apparatus separates naturally into two fundamental classes: First, slime, i.e., suspended matter or material which will not settle and which floats along over the jig; second, gravel and sand, i.e., material which will settle. Therefore, in bringing out ideal concentrator down to a practical basis, we must provide a device for separating the suspended matter or slime as an unfinished product for subsequent treatment; at the same time, the apparatus must be capable of stratifying and separating from a mixed feed the free mineral and middling from the gangue.

The Woodbury Slime Classifying Jig.

Such an apparatus has actually been brought out, and is being manufactured by the Power & Mining Machinery Company, of Cudahy, Wis., viz., the Woodbury Slime Classifying Jig.

This machine is a development of careful experimental work, and is in practical use at the great Calumet & Hecla mills at Lake Linden, Michigan, and other large plants throughout the world.

It is a refinement of former types of plunger jigs, so arranged that the feed flowing onto the jigs parallels the currents of water, caused by the plunger impulse, enabling the jig to rapidly stratify the sands and gravel in an absolutely mixed feed. An unsized ore (not coarser than minus ⅜-in. round) is delivered at the head of the unit to the first compartment—the slime classifying jig.

This compartment is a jig of the plunger type 24 in. wide. The feed flowing over the sieve quickly separates into its two fundamental classes, viz., suspended matter or slime, and sand and gravel which settles and is stratified. The latter is thoroughly scrubbed free of slime, which is held in suspension by the hutch water, introduced under the plunger.

Slime Discharge.

A device for skimming off the slime in suspension delivers a dense original slime from this compartment as a product for further treatment on suitable tables. This separation is positive and complete, the gravel and sand on the sieve acting as a sand filter and being itself discharged thoroughly freed of all slime. At the same time this classifying jig performs all the regular functions of a jig, and separates a large tonnage of clean cup and hutch mineral, usually from 50 per cent to 60 per cent of all free mineral being separated on this slime classifying jig.

The second compartment, which follows the jig described above, is a clean-up jig for completing the separation of free mineral. This jig is 48 in. wide and usually discharges two finished products, viz., cup and hutch concentrates. The tailings from jig No. 2 pass to jigs No. 3 and No. 4 which are termed middling jigs, and are provided with suitable middling discharges.

Hydraulic Middling Discharge.

These middling jigs are equipped with a very efficient device for discharging middling from an unsized feed, viz., the hydraulic middling discharge. An angle-iron shield is fastened across the tail of the jig, extending down into the middling stratum which seals it against the entrance of tailing. From under this shield a number of openings placed at intervals of 6 in. lead into a hydraulic chamber. A fresh water supply therein, under valve control, regulates the quantity and quality of middling discharged from under shield through these openings into the hydraulic compartment and out through plugs in the bottom. The advantages of this device are (1) a uniform discharge over entire width of jig; (2) the separating and discharging of a true middling as stratified on the jig, the hy-

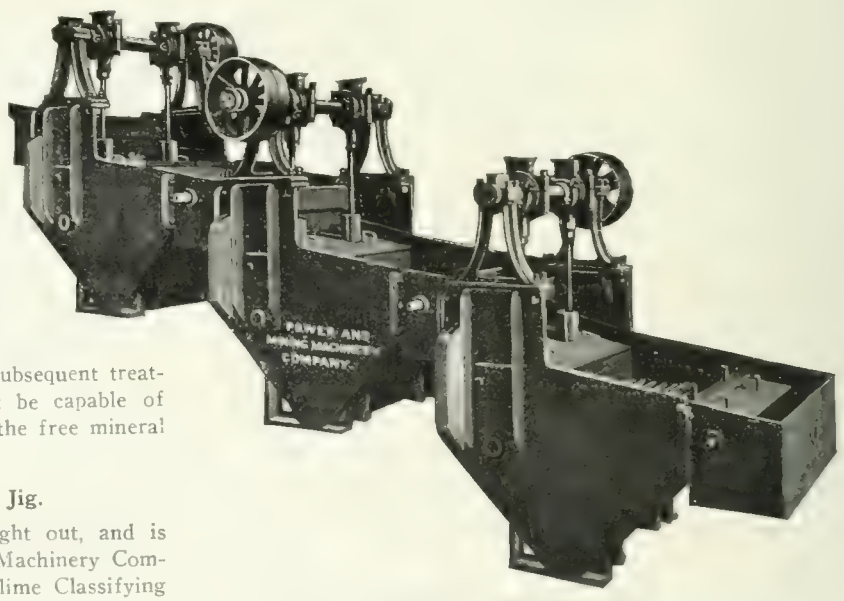

FIG. 3.—WOODBURY JIGS.

draulic water controlling same and holding back any light tailing material.

Water-Saving Device.

An important feature of these jigs is the water lessener, a device for diverting the excess water in the feed into the hutch of the next succeeding jig. The tailing from one jig passes over the angle-iron shield and hydraulic compartment to the water lessener box of the next succeeding jig, from which it is discharged through plugs over plunger compartment and becomes the feed for the next compartment. The surplus water which cannot discharge through the plugs flows over the top of lessener into a trough communicating with the hutch under the plunger, thus effecting a very material saving in hutch water as well as reducing the quantity of top water which otherwise accumulates and tends to carry off the light mineral.

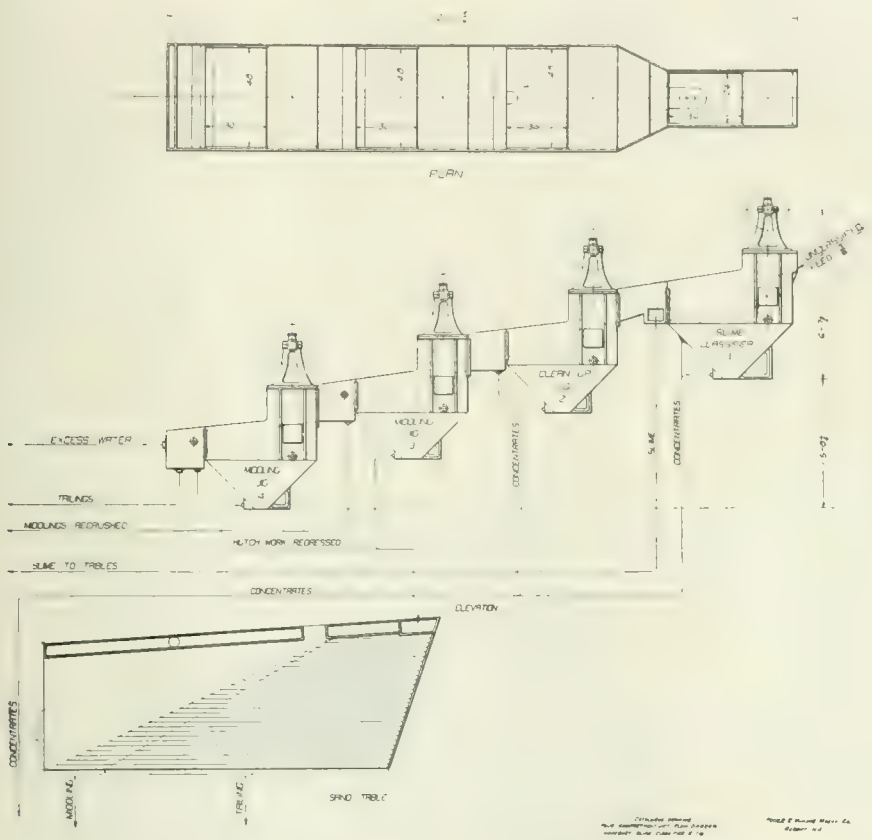

FIG. 5.—APPLICATION OF WOODBURY SYSTEM TO FINE CONCENTRATION.

Hutch Work.

The material discharged from the hutches of jig compartments Nos. 1 and 2 is usually clean mineral, and is included in the general concentrate. From the hutches of the middling jigs is obtained an enriched sand containing any light fine mineral which may have been carried over from the second compartment, this sand usually being redressed on a table of the Wilfley type. From the end of the last compartment a tailing is discharged to waste, the same having been freed, as above described, of slime, free mineral, middling and table sand.

To summarize, therefore, we have a means of handling a mixed feed without preliminary sizing, in large unit tonnages, which will classify same into the desired products:

(1) Slime (approximately 60 mesh and finer), for subsequent treatment on tables.
(2) Concentrates.
(3) Middlings, for regrinding.
(4) Hutch sands, for further table treatment.
(5) Tailings to waste.

General Application.

The writer has applied this mixed feed system, as heretofore described, to various kinds of jigging ores, including native and sulphide copper, lead, zinc, tin, iron and sapphires, and has thoroughly demonstrated its practicability and superiority in coarse, medium and fine jigging. Any ore amenable to wet concentration can be handled to advantage with this system. In ores other than native copper, the mineral is usually softer and more friable than the gangue, and in the process of crushing is more easily slimed. It is therefore advisable to begin concentration as early in the process as possible, in order to recover the valuable mineral as soon as liberated and before it is slimed by further crushing. The proper limiting size at which concentration should begin varies materially on different ores, in some the mineral being liberated during coarse crushing, while in others it is so finely disseminated as to need pulverizing.

Inasmuch as the Woodbury machines will treat unsized ores, preliminary sizing is unnecessary, except where material coarser than ⅜ in. is to be concentrated, when a screen separation is necessary at ⅜ in., the oversize being treated on coarse jigs and the undersize on the classifier jigs. The material coarser than ⅜ in. is treated without further sizing on special jigs, having adjustments and discharges suited to coarse material. When the maximum size of the ore is not over ¾ in., the 48-in. Woodbury oversize jig is used; on a larger maximum size the 60-in. Woodbury bull jig. The undersize of ⅜-in. screens is treated without further sizing on the classifier and jigs.

Roughing Free Mineral and Slime from a Mixed Feed, No Tailing Discarded

Where it is desired to rough out the free mineral before grinding, nothing approaches the simplicity of this arrangement, as the ore from the crushers has simply to be screened at ⅜-in., the coarse mineral in the oversize being separated on an oversize or bull jig, and the free mineral and slime in the undersize being separated on the two-compartment classifier jigs. The rich original slime is gotten out of the system without undue dilution and is passed on to the slime department. The tailing from the roughing jig is recrushed, the coarse jig tailing being crushed to ⅜ in., while the classifier jig tailing is finely pulverized and retreated. In case the mineral is not freed by coarse crushing in sufficient quantity for jigging, the coarse jigs are omitted and the classifier jigs only used as roughing machines.

Ores such as brown and red hematite, coal, pyrite, chalcocite, and chalcopyrite can be roughed in immense tonnages and with great economy in floor space, water, attendance, etc. The unfinished products, slime and middling, are in far better condition than under the sizing system, the slime being dense, not coarser than 60-mesh, and separated at the head of the mill. The middling is a thoroughly classified included product, being cleaned of free mineral which otherwise would be slimed in the regrinding.

Finishing Jigs for Medium Ores, Tailing Being Discarded.

The Woodbury slime classifier and clean-up jig (two compartments only) is required to clean the free mineral and slime from an unsized feed. When it is desired, however, to finish the operation by separating the middling material for regrind-

ing, two middling jigs are usually added to the unit, making the standard finishing unit four compartments in all.

A finishing unit of jigs will handle approximately 250 tons per 24 hours, and as heretofore described, separates the following products: slime, concentrate, middling, table sand and tailing. The feed is unsized and may be the undersize of any size screen not to exceed ⅜ in. round.

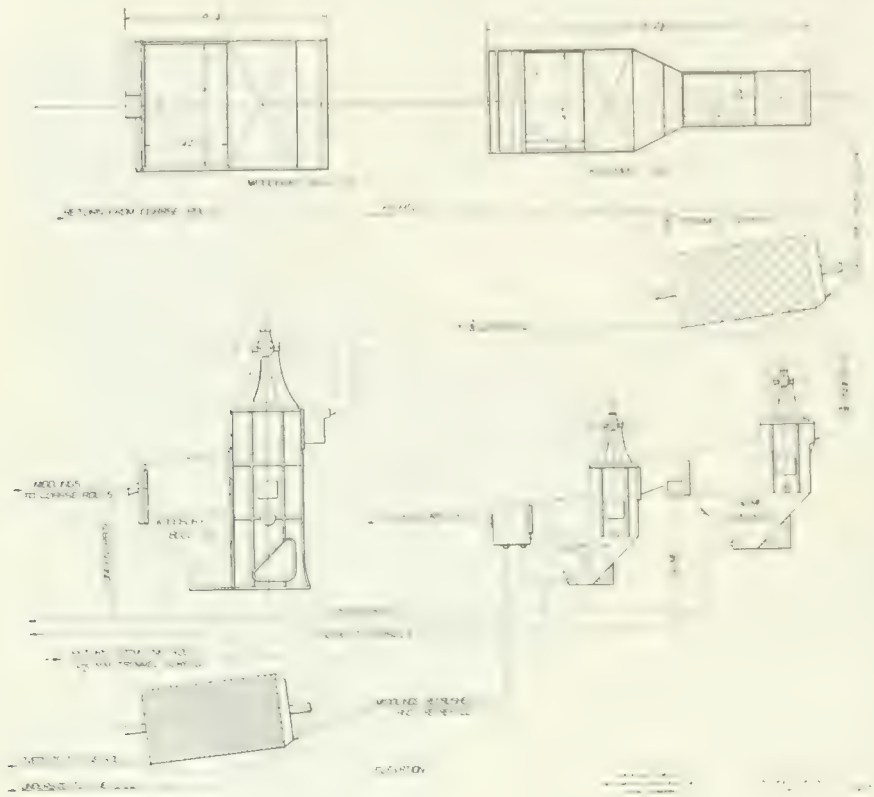

FIG. 4.—SHOWING APPLICATION TO COARSE CONCENTRATION.

The advantages of the system on finishing work are very marked; a dense slime, clean concentrate and well-classified middling being separated with lowered tailing loss. Considerable economy is effected in water, floor space and attendance, and the mill greatly simplified. It should be noted that hydraulic classification and fine screening are entirely eliminated in this system.

Complex Ores.

Where it is necessary to separate two minerals of different specific gravity, a unit of five or even six compartments is required. The slime is separated as above on the first compartment, the heavier mineral on compartments Nos. 1 and 2, the lighter mineral on Nos. 3 and 4, and middling on Nos. 5 and 6, a tailing being discharged from the end of the unit.

The "luminator" purification treatment of water for steam boilers consists in passing the water through an aluminum trough or launder, exposed to sunlight, whereby the deposition of hard scale in the boilers is avoided. The theory of its operation is thought to be electrical, as suggested by several contributors to the *Journal* of the Chem. Met. & Min. Soc., of S. Africa. A galvanometer connected to an aluminum plate over which water was flowing, and to an iron tank in which the water was received, showed a deflection equivalent to from 1 to 4 milli-volts. An explanation of the result is that the aluminum is changed into aluminum hydroxide, which, in an alkaline water, might pass into solution as an aluminate and precipitate salts of calcium and magnesium.

Steam Trap System.

At the saltpetre works of Battelle & Renwick, Jersey City, N. J., a novel steam trap system has recently been started up, which takes care of all the condensation from all the apparatus throughout the mill and returns the same to the boilers. This system not only takes care of all the condensation, but it is so arranged that the waste vapor from the vents of the traps is condensed and returned with the regular condensation.

The mill apparatus consists of nineteen special kettles for boiling. Each kettle is equipped with what is known as a pit coil, that is, the drip from the coil instead of passing through the bottom of the kettle is carried up over the edge, so that the water of condensation is raised 6 ft. before it is discharged. There is also a dry room and drying machines included in the system. The approximate amount of steam required for boiling alone is about 600 hp. The boiling point of some of the liquids in the kettles is as high as 270 deg. Therefore, live steam is required for this work.

On account of the nature of the coils it has been impossible to use ordinary traps on this work, but each coil at the present time is equipped with a special No. 20 Lytton trap which discharges into the return main, of which two are used, running through the factory and back to a receiving tank in the boiler room. The temperature of this return water varies from 260 to 282 deg.

All the vapor from these special traps is used for drying purposes and when condensed is also returned to the boilers, so that no steam or vapor is allowed to blow into the atmosphere.

On the boilers are located two 4-in. return traps and one 1½-in. return trap, which take care of the return water from the factory at the temperatures mentioned and return it automatically to the boilers.

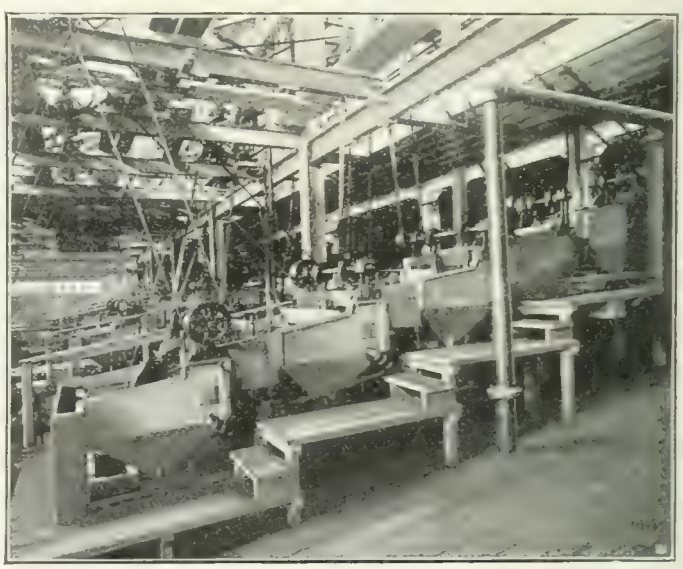

FIG. 6.—WOODBURY SYSTEM APPLIED TO "COARSE" ORES, 500-TON UNIT.

The condensation from the live steam mains is also trapped and collected in a separate return which discharges into the receiver in the boiler room.

By the installation of this system the saving in coal alone amounts to 2½ tons per day, while the boiling capacity of quite a number of the kettles is increased from 15 to 25 per cent.

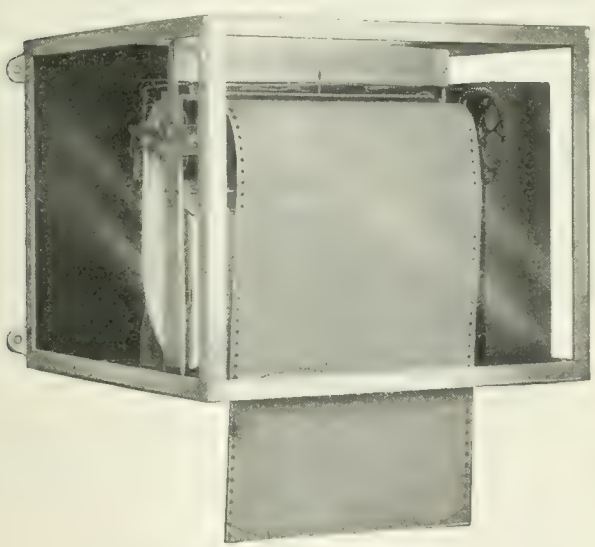
It has not only made quite a saving in coal and increased capacity of the kettles, but it is feeding the boilers with about 90 per cent of pure water, which prevents the formation of scale and also makes an additional saving in the amount of extra water that would have to be purchased from the city.

This system was devised by Mr. D. J. Lewis, Jr., sales manager and trap expert of the Lytton Manufacturing Corporation, and consists of twenty-six Lytton traps, three of which are return traps and the balance regular and special 20 series traps.

Continuous Chart Recording Pyrometer.

The Brown Instrument Company, of Philadelphia, and its associate company, the Keystone Electrical Instrument Company, have brought out a new continuous chart recording instrument, particularly designed for use as a pyrometer, but which can also be used for indicating volts, amperes, revolutions per minute, mechanical operations, etc., where a small current of electricity is required to operate a recording instrument.

This new instrument is of the frictionless type, the pen making a single dot of ink momentarily on the paper at short intervals, every 10 seconds, or every minute as desired, and



CONTINUOUS CHART RECORDING PYROMETER.

these dots practically form a continuous line. The instrument carries a 6 months roll of recording paper, traveling a little over an inch an hour which does away with the necessity of changing the charts daily, and for many operations the continuous chart is preferable. The record can either be torn off as desired every day or once a week, or it can be allowed to roll up continuously.

This new instrument as shown in the adjoining illustration is handsome, simple and practical.

American Vanadium Facts for October, issued by the American Vanadium Company, of Pittsburgh, Pa., contains some very interesting notes on vanadium steel in the machine shop, on vanadium rock drill steel, on a remarkable test of chrome-vanadium steel tire, and on the use of vanadium steel in automobile construction for springs and gears.

A New British Electric Steel Plant.

As a result of some two years' experience in electric steel melting furnaces the Stobie Steel Company of Sheffield, England, is building a new steel works in which all the melting and further treatment of the steel will be electrical. This will be the first big steel works in Great Britain solely engaged on the electrical manufacture of tool steels, alloy steels, and similar material.

The new works are being erected on the Tyne side as current can be obtained on the North East Coast under more favorable conditions than in Sheffield.

The installations will, at first, consist of a 15-ton, three-phase steel melting furnace, a 5-ton, two-phase one for special steels, and a 3-cwt alloy melting furnace. All these furnaces are designed and built by Mr. Victor Stobie who has made a special study of electric steel furnaces from the metallurgical point of view while maintaining all electrical requirements and improvements which help to make the furnace a good load for the power station.

A 2-ton Stobie electric steel melting furnace is shortly being built for another Sheffield steel works and a 15-ton furnace is also projected for a steel works in the north.

Bureau of Standards Analyzed Samples

The Bureau of Standards, Washington, D. C., is now prepared to issue pure sodium oxalate for use as a standard in oxidimetry, in bottles containing 120 and 200 grams, the fees for which are respectively $2.00 and $3.00. With each sample is furnished a certificate giving the purity of the material and brief directions for its use in the standardization of permanganate solutions.

Circular No. 40, "Sodium Oxalate as a Standard in Volumetric Analysis," is now ready for distribution and will be sent upon request. It includes a description of properties, preparation and testing of sodium oxalate, and a discussion of its suitability as a standard in oxidimetry and acidimetry.

The fourth edition of Circular 25, "Standard Analyzed Samples—General Information," is now ready for distribution. Attention is called to the fact that the fee for sample No. 24, Vanadium Steel, has been changed from $2.00 to $2.50.

Chrome-tungsten Steel, No. 31, is now ready for distribution.

Another Cement Mill for California

The Old Mission Portland Cement Company announces that their mill at San Juan, San Benito County, Cal. (formerly the San Juan Portland Cement Company) is to be completed and put in operation in the near future.

The firm of Smith, Emery & Company, Industrial Engineers, at San Francisco and Los Angeles, have been engaged to design and erect the mill.

It is expected that the output of this mill will be a factor in the market next Spring.

Electric Equipment of the New Aluminium Works in North Carolina.

Seven vertical waterwheel type electric generators, which represent units of the largest rating ever built for generating direct current, will be installed in the new plant of the Southern Aluminium Company at Whitney, N. C. Each machine will have a rating of 5000 kw, delivering 20,000 amp at 250 volts and operating at a speed of 170 r.p.m. Two smaller direct-current generators of the same type, rated at 2500 kw at 300 r.p.m.; two 1250-kva alternators, having a speed of 514 r.p.m., with two 10-kw exciters, and all necessary switchboard and controlling

devices are also included in the installation, which will be one of the largest and most modern of its kind in the world. It is the intention of the Southern Aluminium Company to push to completion the project now under way and to have in operation in the course of the next eight months a manufacturing plant that will turn out some 25,000 tons of aluminium annually.

The company was recently incorporated under the laws of the State of New York with a capitalization of $8,000,000 and was organized by some of the largest aluminium manufacturing companies of Europe. The enterprise has been financed in France and is closely associated with l'Aluminium Français, of Paris. The work at Whitney is in charge of Dr. Paul Heroult. Although he has been directing constructive operations there only a few weeks, remarkable progress has been made, and it is confidently expected that the entire plant will be in readiness for turning out the product of the company by the middle of 1914.

In the complement of buildings are nine furnace rooms, wherein the alumina will undergo the various processes incidental to conversion into aluminium. Each of these structures measures 60 ft. by 500 ft., and one electrode factory of similar dimensions is also included in the group.

The generators will be installed immediately over wheel pits and directly connected to vertical shafts of S. Morgan Smith turbines by forged steel flanged couplings. Each 5000-kw generator will weigh in the neighborhood of 150 tons, measure 22 ft. in diameter and extend 13 ft. above the floor level. The entire rotating element of the generators will be supported from an overhead thrust bearing. While the normal speed will be 170 r.p.m., they will be designed with provision for a safety runaway speed of 75 per cent above normal. The wheel governors will be provided with remote electric control for both hand and automatic operation. The electrical equipment will be supplied by the General Electric Company.

Personal.

Mr. **T. M. Caven,** designer of electric heating appliances, has resigned as manager of the Bon Ami Electric Company, Milwaukee, to become manager of the electrical department of the Kieselguhr Company of America, with office at 1633 Monadnock Building, Chicago. Kieselguhr is a natural mineral product, consisting mainly of silica, and is used for a variety of purposes, including heat and electrical insulation. Mr. Caven is interested in pointing out the possibilities of kieselguhr in electric furnace and electric oven work.

Mr. **C. A. H. de Saulles,** son of Major de Saulles, of the New Jersey Zinc Company, has taken a position as manager of the zinc interests of the American Smelting & Refining Company, with headquarters at 165 Broadway, New York City. Mr. de Saulles was brought up in the zinc business and was general manager of the Prime Western Spelter Company (the New Jersey Zinc Company's Western concern). Fifteen years ago he was famous as Yale quarter-back and made the de Saulles runs against Harvard and Princeton.

Mr. **Otto Frick,** the inventor of the Frick induction furnace, has arrived in this country for the purpose of introducing the latest types of induction furnaces for the iron and steel industry, which are handled by Dr. Karl Georg Frank, of New York City, representing the Siemens & Halske Company, of Germany. The furnaces to be installed in the United States will be made in this country.

Mr. **L. E. Ives** has resigned as associate editor of the *Engineering and Mining Journal*, and will hereafter be on the editorial staff of the *Iron Trade Review* as mining and assistant engineering editor.

Messrs. **Joseph A. Richards, Lucius I. Wightman** and **Paul Morse Richards** announce the formationn of the firm of Wightman & Richards, counsellors and consulting engineers in technical advertising and marketing, with offices at 29 Broadway, New York City. Mr. Joseph A. Richards is the head of the general advertising agency having his name Mr. Wightman, a graduate of the University of Colorado, has held during the past twelve years various engineering and business positions and has been quite active as a technical writer and author.

Dr. **Wilhelm Schumacher,** of Berlin, the well-known expert on the briquetting of flue dust and iron ores, has arrived in this country on an inspection trip in the interests of the General Briquetting Company, who represent the Schumacher process in the United States. Dr. Schumacher is now in Buffalo looking over his process, which has recently been installed at the works of the Lackawanna Steel Company.

Professor **Clarence P. Linville,** after a service of nine years in charge of the department of metallurgical engineering and as professor of metallurgy at the Pennsylvania State College, has resigned to accept the position of superintendent of blast furnaces with Joseph E. Thropp, and is now located at Earlston (Everett Post Office), Bedford County, Pennsylvania.

Sir William Ramsay, K. C. B., of London, is delivering a series of three lectures on the gases of the atmosphere before the Department of Chemistry of the Polytechnic Institute of Brooklyn, N. Y. All three lectures are held Tuesday evenings at 8:15. The first lectures were delivered on October 22 on the ancient history of the gases of the atmosphere, and on October 29 on the discovery of argon, helium, neon, krypton and xenon. The last lecture will be held on November 5 on niton, or the radium emanation.

Mr. **Kilburn D. Clark,** formerly representative of the Harbison-Walker Refractories Company in New York State and Canada, has secured the representation in the same district for the General Refractories Company, manufacturers of the highest grade fire brick, silica, magnesia and chrome brick, fire clay, silica cement, and importers of magnesite and chrome ore; also the Brighton Fire Brick Company, manufacturers of several grades of fire brick. The main office will be 75 Erie County Bank Building, Buffalo, N. Y.

Obituary.

Mr. **William Horace Corbin,** vice-president of the Joseph Dixon Crucible Company, died on September 25.

Mr. **Frederick J. Mayer,** the highly distinguished gas engineer, former chief engineer of the Bartlett & Hayward Company, and later founder and general manager of the Didier-March Company, died at the age of 59 years.

Dr. **William S. Weedon,** research chemist with the E. I. du Pont de Nemours Powder Company, and formerly with the General Electric Company, died on July 10 at the age of 35 years.

Mr. **Maunsel White,** one of the inventors of the Taylor-White process for the heat treatment of tool steels, died in New Orleans, La., on October 22.

Notes.

The **Electric Furnace Company,** of Alliance, Ohio, designers and builders of the Baily electric furnace for heating bars, billets and ingots, have opened an office in the Oliver Building in Pittsburgh, in charge of Mr. F. M. Rush, and an office in Cleveland, in charge of Mr. F. B. Allen.

The **Primos Chemical Company,** manufacturers of ferro-alloys and pure metals, have rebuilt the burned part of their works at Primos, which is now again in full operation. The new plant is entirely built of brick and iron and is fireproof.

The **Prest-O-Lite Company,** Indianapolis, Ind., for their new plant now building, have placed contract with Rockwell Furnace Company, New York, for a complete installation of oil-fired furnaces and ovens. The furnaces are the Rock-

well over fired accurate temperature type, and will be used for heat treatment. The ovens, car type, will be used for baking asbestos disks. The installation, a large one, will have a capacity of heat treating 1200 tanks a day.

Wilfley Table.—We have received from the Mine and Smelter Supply Company, of Denver, Col., their illustrated Bulletin No. 25, on the No. 6 Wilfley concentrator. After a general description of the Wilfley table, with special reference to the improvements embraced in the No. 6 type, the methods of erecting and operating the table are described in some detail and the fundamental principles of the table are explained.

The **Titanium Alloy Manufacturing Company** has removed their general sales department to their works at Niagara Falls, N. Y., where their electric furnace plant is located, and has created a district office at Pittsburgh, where the usual work with the iron and steel trade will be continued.

The **Crucible Steel Company of America** has bought, according to the Syracuse "Post Standard," fifty acres of land adjoining the site of the Halcomb Steel Company. The next directors' meeting is expected to decide to move the Sanderson Works from their present place to this new location. There are shipping facilities on the Lackawanna Railroad and by water.

The Denver Fire Clay Company, Denver, Colo., has just issued its 1913 catalogue of assayers' and chemists supplies. The book is cloth-bound, contains 530 pages and numerous illustrations, and is more elaborate than any catalogue yet issued by the company. The contents are classified under five heads: assayers' and chemists' laboratory supplies, such as balances, crushing and grinding machinery, furnaces and general apparatus; estimates on equipment for assayers', prospectors', school laboratories; fire-clay, brick and tile; scientific books, and chemicals and reagents. A complete index renders the catalogue useful.

Digest of Electrochemical U. S. Patents

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (*Continued*).

605,835, June 21, 1898, Emile Andreoli and Gabriel Andreoli, of London, England.

Relates to the formation of an amalgam from a concentrated chloride of sodium solution, and the coating of copper or other metal plates with mercury electrolytically so as to render them available for the recovery of gold or silver by amalgamation, or in the mortar mill where the auriferous ores are crushed.

The apparatus consists of an electrolyzer and of an amalgamator similar to the electrolyzer. The electrolyzer is of slate or earthenware, etc., and is divided by a suitable diaphragm into anode and cathode compartments. The anode is of iron or other suitable material, and the cathode of mercury. The anode compartment contains the sodium chloride, the cathode compartment being filled with water. The sodium amalgam is tapped from the electrolyzer to the amalgamator and replaced by fresh mercury, fresh sodium chloride being added to the anode compartment. In the amalgamator the copper or other plate is coated with amalgam; the latter may if desired be continually enriched by the electrolysis of sodium chloride; or the preliminary process in the electrolyzer may be omitted, the entire process being carried on in the amalgamator. The cathode compartment of the latter contains a central shelf of inert material, leaving a narrow space along the side of the diaphragm, thereby economizing in mercury. The copper plate is laid on this shelf and covered with a layer of mercury or dipped down in the narrow vertical space at the side of the diaphragm.

614,572, Nov. 22, 1898, Joseph G. McNulty, of New York, N. Y.

Relates to a method and apparatus for treating ore. The apparatus consists of one or more pairs of tanks in which are suspended electrodes and through which flows a stream of finely divided ore held in suspension, as a pulp, in an electrolyte. The anodes are preferably of lead, the cathodes of amalgamated copper. The pulp flows in at the bottom and upwards through the first tank, and down through the second, the electrodes vibrating transversely in the flowing stream. The free metallic precious metal is amalgamated on the cathodes, and any dissolved metal electrolytically precipitated. The electrodes are vibrated "broadside" by a rotating cam above the tanks, which moves the support for the suspended plates.

616,891, Jan. 3, 1899, George D. Burton, of Boston, Massachusetts.

Relates to apparatus for treating metals and ores, and consists of a tank containing a plurality of superimposed perforated deflecting plates immersed in an electrolyte, which distribute the ore, etc., in fine streams, and facilitate its solution in the electrolyte. At the bottom of the tank is a moving belt carrying buckets which collect the sand, etc., falling through the electrolyte, and carry it out of the solution. The electrolyte is in constant circulation. Electrodes are placed on opposite vertical sides of the deflector plates; the latter being connected to the cathode.

With copper ore, an electrolyte of sulphuric acid is used; the ore is fed to the immersed screens or deflectors, the copper dissolved by the acid and deposited upon the cathodes, the insoluble residue passing through the perforations and settling upon the traveling belt which carries it out of the tank.

617,512, Jan. 10, 1899, Lewis E. Porter, of Los Angeles, California, assignor to The Porter Gold and Silver Extraction Company, of California.

Relates to apparatus for extracting precious metals from ores, and consists of a rotating barrel supported upon a hollow shaft, the shaft carrying anodes and cathodes, the latter suitably covered with canvas, etc. Within the tank, next to the wall, are several layers of coarse and fine wire screen, and between them in the center, a layer of asbestos or other filtering material; the two outermost layers being of coarse wire. The barrel may be rotated at high and low speeds; when rotating at a high speed, it acts as a centrifugal filter, the liquid filtering off through the asbestos and out of suitable openings. The solution may consist of water containing enough sodium chloride to give it conductivity, from about ¼ to 3 per cent; cyanide of potash, ¼ of 1 per cent; and enough caustic soda to neutralize any acid in the ore. About 1 ton of solution will treat about 3 tons of ore. The mixed ore and solution are fed into the barrel which is rotated slowly, the current turned on, and the ore treated chemically and electrochemically, the metal being deposited on the cathode. When the process is completed, the barrel is rotated at a higher speed, and all liquid separated; water is then added through the hollow shaft, and the ore washed; additional water is now added to bring the ore to a slush, which is then removed from the tank, and a fresh charge added.

617,911, Jan. 17, 1899, Elias Anthon Smith and Markus Hartmann Lyng, of Anaconda, Mont.

Relates to a method of extracting metals from ores. A suitable rotary tank, having an acid-proof lining, is charged with copper ore, sulphuric acid and 10 to 15 per cent of manganese dioxide; the sulphuric acid being present in sufficient quantity to convert the metals, including manganese, to sulphate, with a slight excess. The tank is rotated slowly, and hot air from 40 to 80 lb. per square inch pressure is pumped in the tank. The metals present, except gold, are converted into sulphates, the action continuing from 4 to 16 hours. The solution is drained off, settled, and the clear solution run over copper filings to pre-

cipitate any silver; the remaining solution is electrolyzed, separating copper at the cathode and manganese dioxide at the anode. The remaining electrolyte is evaporated to crystallize out any copper sulphate or manganese sulphate, the sulphuric acid remaining being now in condition for re-use in the digester with fresh ore. If gold is present, the tailings from the the first treatment are digested a second time with manganese dioxide and hydrochloric acid, the chloride of the gold being recovered and treated as usual.

BOOK REVIEWS.

Lehrbuch der Chemischen Technologie und Metallurgie. Edited by Dr. Bernhard Neumann, Professor in the Technical High School in Darmstadt. Large octavo, 17 x 24 cm., 891 pages, 398 illustrations. Price, 19.60 marks (in New York, $6.00). Leipzig: S. Hirzel.

This is a collection of forty-five chapters, varying in length from 2 to 100 pages, written by the editor and his 18 collaborateurs. The space is too restricted for compendious treatment of any one subject, but the style is short and condensed, and there is an immense amount of information, correct and very well brought up to date, within the covers of this book. The topics are: Water, Liquid Air and Compressed Gases, Combustibles, Illuminating Gas, Coke, Turf, Charcoal, Salt, Potash Salts, Sulphuric Acid, Hydrochloric Acid, Nitric Acid, Hydrofluoric and Phosphoric Acids, Soda, Electrolytic Alkali, Ammonia and Cyanides, Alumina, Aluminum and Ultra-Marine, Magnesium, Calcium and Barium Compounds, Per-oxides and Per-salts, Fertilizers, Cements, Stoneware, Glass, Iron, Other Metals, Explosives, Mineral Oil, Asphalt, Mineral Wax, Distillation of Tar, Acetic Acid, Methyl Alcohol and Acetone, Fats and Soaps, Rubber, Glue, Tanning, Beet Sugar, Starch, Fermentation, Wine, Beer, Spirits, Cellulose and Artificial Silk, Textiles, Dyes, Dyeing. The work is a splendid reference book for these subjects, for students, engineers or manufacturers.

* * *

Cast Iron, in the Light of Recent Research. By W. H. Hatfield. Octavo, 16 x 22½ cm., 249 pages, 164 illustrations, including many microphotographs. Price $3.50. London: Chas. Griffin & Co., Ltd. Philadelphia: J. B. Lippincott Co.

This should be a very useful book to the worker in cast iron and users of the same. Separate chapters treat on the influence of silicon, phosphorous, sulphur, manganese, and other elements. Other chapters handle casting temperature, shrinkage, growth by repeated heatings, effect of superheated steam, heat treatment, decarburization, malleable cast iron, furnaces and slags, and the mechanical properties and testing. The author's discussion of the malleablizing process is interesting. His investigations support Ledebur's original theory and negative Wüst's conclusions. It is a cleancut, practical and commendable treatise.

* * *

The Metallography of Iron and Steel. By **Albert Sauveur.** 7 x 10½ in. (17½ x 27 cm.), perhaps 280 pages, doubtless over 300 illustrations, plate paper throughout; price $6.00 net. Cambridge, Mass.: Sauveur and Boylston.

The contents comprise a chapter of thirty-five pages on apparatus for the metallographic laboratory, thirty-four "Lessons," of eight to thirty pages length, each paged separately, one appendix on "Manipulations" and another on "Nomenclature."

The separate paging of each lesson, and separate numbering of the illustrations in each, made it impracticable for the reviewer to state the number of pages or of illustrations in the book. Others besides the reviewer are going to find inconvenience in this unusual arrangement: any reference to data in the book will have to comprise both "Lesson" and page. The consecutive numbering of the pages and illustrations in the next edition will cost the publishers a few dollars extra, but it is a false economy not to make the outlay.

As for the book itself, it is very satisfactory. The illustrations are fine, and beautifully set off on the smooth calendered paper. The text is clear and definite, giving the beginner sure and sound foundation stones on which to build securely his subsequent work. In this respect it is the best text on metallography for beginners, and the clearest guide to further study, that we have seen. The auxiliary metallurgical information is unusually lucid and well-classified.

We are glad to commend the work highly to students of metallography.

* * *

Introduction à l'Etude de la Metallurgie. Part I: Le Chauffage Industriel. By **Henry Le Chatelier.** 16 x 24 centimeters, 528 pages, 96 illustrations; price 12 francs, bound, 15.50. Paris: H. Dunod and E. Pinat.

The ten chapters deal with: Industrial Science, Phenomena of Combustion, Calorific Efficiency, Natural Fuels, Charcoal and Coke, Acetylene and Water Gas, Illuminating Gas, Producer Gas, Refractory Materials, Furnaces. Part II, dealing with metals and alloys, will constitute a separate volume.

The preface strikes the keynote of the work, saying: "The teaching in our higher technical schools ought to become scientific, and should no longer content itself with being simply professional." Following this idea, the whole of this work is concerned with the why and wherefore, the scientific explanation, of heating and combustion, with only sufficient description to serve as a skeleton or framework for the discussions of principles.

This method is the best possible, provided it is supplemented by lectures which put spice into and give zest to the subject. Professor Le Chatelier, with his rich supply of specimens, models, pictures and diagrams, no doubt makes the subject-matter of the book highly attractive; but the book would be dry work for the student without some such illustration. Furthermore, while the work may be suited to French students and teachers, we doubt its usefulness outside of this limited circle, except to a few specialists in combustion. The latter will find in it useful ideas on the nature of flame and the propagation of combustion.

Volume II of the Annual Tables of Constants and Numerical Data, Chemical, Physical and Technological, edited and published by an International Commission created by the Seventh International Congress of Applied Chemistry and continued by the Eighth Congress, is now in press and will be issued about January 1, 1913. Volume I, which was issued early this year, was sold to subscribers at $5.00 (unbound). The volume proved to be about 50 per cent larger than the International Commission had anticipated. The second volume will have to be issued at a somewhat higher price, the exact amount of which has not yet been determined upon. *Subscribers* to the second volume, whose subscriptions are received before January 1 by Dr. Charles Marie, secretary of the Commission, 9 rue des Bagneux, Paris, France, or by the University of Chicago Press, Chicago, American Publishers, will be entitled to receive the volume at the price at which it is issued to subscribers and will have the right to cancel their subscriptions within four weeks after the price is announced. Subscriptions should therefore be sent at once. Payment of the subscription will be made to the University of Chicago Press, when the volume is published. The price of the volume will be materially higher for non-subscribers, as only a limited number of copies beyond those subscribed for will be printed. Further information may be secured from the above addresses or from any one of the American Commissioners, Dr. Julius Stieglitz, University of Chicago, Dr. E. C. Franklin, Bureau of Hygiene, Washington, D. C., G. F. Hull, Dartmouth College, Hanover, N. H.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Vol. X — New York, December, 1912. — No. 12

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

J. W. Richards, Ph.D., President.
James H. McGraw, Vice-President.
Curtis E. Whittlesey, Treasurer. E. F. Roeber, Secretary.

Cleveland Meeting of the American Institute of Mining Engineers.

So much had been written and so much more had been said about the present situation in the American Institute of Mining Engineers that the outcome of the Cleveland meeting was awaited with the greatest interest by everyone. For this reason and because of the brilliant success achieved, it is a real pleasure to devote a large portion of this issue to the report of this meeting.

If any proof was necessary that the Institute in itself is as healthy and vigorous as in its youngest days, it was supplied in striking manner by the Cleveland meeting. Brilliant in its professional sessions and delightful in its social functions, it also was a symptom of the much talked-of "rejuvenation" of the Institute, as it was the first meeting held under the auspices of the newly founded Iron and Steel Division. There was a glorious array of papers on iron and steel metallurgy—all on hand in print or mimeographed and all eliciting interesting discussion. And yet the final touch was occasionally put on the discussion by the remark of an "outsider," as in the discussion of the function of alumina in iron blast-furnace slags, with which we deal in a separate editorial note on "the value of theory in metallurgical practice" on the following page. Such is the true function of a broad professional institution—to let every man specialize to his heart's desire and still keep him in close touch with his fellow workers in other fields.

It was a truly representative meeting and it augurs well for the future usefulness of the Institute. That in its present state of evolution, not everyone agrees with everyone as to details of policy, is only natural. It is natural that opinions should differ whether to change from a benevolent monarchy to a true democracy or to an oligarchy of "Fellows" although the answer which will be given by the whole membership can hardly be in doubt.

The idea of a special class of Fellows has in itself a few strong points. That engineers must take in future a decided stand on certain broad problems, is a point we have made only recently in connection with the deplorable cessation of power development at Niagara. But where to draw the line and whether it is necessary to create for this purpose a class of Fellows, are other questions.

All these questions will be worked out in time. The most urgent need in the present rejuvenation of the Institute is rejuvenation of membership. The attendance at Cleveland was perhaps too representative of the "stars" of the profession. It is suggestive to think of the amount of good that could have been done if twice as many of the young men had been there to derive inspiration from mingling with the leaders of the profession. Whether there shall be a selected class of Fellows or not, is relatively unimportant. The important problem is to "rope in" the young fellows—those who will be the leaders of the profession in years to come.

The Value of Theory in Metallurgical Practice.

[illegible] practical problems in the iron and steel industry was very apparent at the recent meeting of the American Institute of Mining Engineers. We prophesy that two papers presented at this meeting will lead to further important research with the equilibrium diagram as a basis, and will go far to revive the hopes for it as a working instrument, which were disappointed because the investigations of Wuest, Goerens, Upton, and others were only partially satisfactory in their practical application, i.e. in explaining certain reactions in the manufacture of malleable cast iron.

Elsewhere in this issue we print practically in full one of these papers by J. E. Johnson, Jr., who is well known to our readers by his brilliant work on dry-blast operation of blast furnaces. Now, in setting himself the problem of improving the quality of charcoal iron, several months' investigation convinced Mr. Johnson that indispensable aids to this solution were: complete chemical analysis, metallographic examination, and finally the assignment of each grade of iron to its proper place in the iron-carbon equilibrium diagram. By these means he has already been able to determine some of the factors which produce good and bad charcoal iron, and thus to manufacture a larger proportion of the former. Incidentally, the investigation has enabled him to give us the first satisfactory explanation of so-called "spotted iron," that anomalous product with a gray exterior and white center, met with especially in Swedish charcoal irons, and which is one of the stumbling blocks of malleable cast-iron manufacture.

The second paper referred to above was by Professor Charles H. Fulton, whose experience has been chiefly with gold and copper metallurgy. He showed in a striking way that a discussion on slags, even by two men, experts in iron blast furnace operation, could not be satisfactorily concluded without a thorough knowledge of the general theoretical principles upon which the fluidity of slags depends, namely, the solution theory and the equilibrium diagram.

And thus we have a paradox, of knowledge which was practical because it was theoretical.

Assailing the Stamp Mill.

In his presidential address before the South African Institution of Engineers, Mr. J. A. Yule reviewed the metallurgical tendencies on the Rand and incidentally touched upon the use of the gravity stamp as a crushing machine. Mr. Yule is not the first to contend that the adaptation of the stamp to coarse crushing is taking that machine out of its legitimate sphere as a pulverizer of ore. This development in stamp crushing has resulted from the general acceptation of the tube mill as a secondary grinder for fine reduction, thus necessitating a greater coarse crushing duty on the part of the stamp.

Although prior to the introduction of the tube mill the stamp was considered an efficient and economical fine grinder, it is not generally conceded that it has retained this position when crushing ore to three or four mesh for subsequent tube milling. In view of the opinions of American Engineers on the subject, most of whom agree with Mr. Yule, it is interesting to note that his further suggestions also coincide with the theory and practice of American mill[illegible] or gyratory crushers, rolls and ball mills as preferable means for coarse and medium crushing.

The water required in the large coarse-crushing South African stamps is greater than was demanded when the stamps were used as fine grinders. In some places this demand has become of material importance; and since there would probably be a reduction in water required by the substitute system mentioned, the latter offers an additional advantage outside the question of crushing efficiency. Water shortage suggests also the value of crushing in cyanide solution, where the recovery of gold and silver is effected mainly by the cyanide process. The Rand has been slow to adopt this practice which has become almost general in America, even where amalgamation and the concentration of sulphide mineral is an adjunct to cyaniding.

The points of capital expenditure and power cost also are touched upon by Mr. Yule, who is of the opinion that both would be reduced by the abandonment of the stamp as a coarse crusher, and the substitution of a two or three-stage system using rolls or ball mills following jaw or gyratory crushers.

While the foregoing is the opinion of the president of a society of engineers, we note also that a South African mining paper has recently ventured the prophecy that the last large Rand mill has been built in which heavy gravity stamps will be used in their present capacity as coarse crushing machines.

A Need in the Metallurgy of Low-Grade Base-Metal Ores.

The problem of how best to treat low-grade base-metal ores is always with us, and offers a fruitful field for speculation and experiment. And yet, with all the processes which have been devised and reached the patent-office stage, it cannot be said that much has been accomplished in a commercially practicable way. The great demand remains unsupplied, viz., some process which will be to low-grade complex base-metal ores what the cyanide process is to low-grade gold and silver ores.

Consider, for example, the comparative simplicity and success of the cyanide process, and its adaptability to small isolated mills and low-grade ores, yielding marketable bullion at the mine. Compare then with this the present series of treatments given to an ore containing small percentages of, say, copper, lead, and zinc, or any two of these metals, no one of which may exist in profitable quantity. Substantially all the metals must be recovered if the ore is to be treated at a profit. But so far as being able to recover these metals at the mine, only the first operation of concentration is performed by the mining company, which then relinquishes its interest in the subsequent operations of smelting and refining which are conducted by foreign companies. The gold-mining operator may build his own reduction plant and produce marketable metal. The base metal miner may only beneficiate his ore, with an attendant loss which may be greater than that sustained in any of the subsequent processes, for which also he has to pay.

The demand, therefore, is for a process which will yield base metals directly to the producer of the ore. Some such processes have been suggested and are under development; others have

not yet been given an opportunity to demonstrate their worth. It is realized that, in stating this demand, a most difficult problem has been stated. But we must realize also that experiments in low-grade base-metal industry ought to follow this line, and that metallurgists and ore-treating companies may well consider researches in this direction, instead of following routine testing along lines already well known and adapted.

The Output of Steel Products.

The American Iron and Steel Association has made public the statistics of the production of rolled iron and rolled steel in the United States in 1911. These statistics are really of more import than the statistics of steel ingots which were published seven months ago, for they refer to steel in its commercial form. The statistics of steel ingot production, generally referred to as the "steel production" have their uses. They furnish a convenient measure either of the growth in capacity of the industry, or the degree of employment of capacity, and they also furnish, what is of perhaps equal importance, a means of measuring the activity of the different steel making processes as classified by the statistical gathering body, acid Bessemer, basic and acid open-hearth, crucible, and electric. *En passant,* it may be remarked that it would be of decided interest if a segregation were made of steel made by the duplex process, now designated merely as basic open-hearth steel. Perhaps the statistical department of the American Iron and Steel Institute, which is to gather the statistics in future since Mr. James M. Swank is retiring after forty years of signally valuable service in this capacity, may be open to suggestions leading to further improvement in American statistics, though it must be confessed that its maiden efforts have not gained for it much prestige.

The statistics of steel ingot production, while useful in certain respects, are not the statistics of the production of commercial steel, for steel is not sold as ingots. The statistics of rolled steel, just published for 1911, refer to steel in its commercial form, substantially the steel after it leaves the last pass in the hot rolls and has been sheared. Thus these statistics include rolled forging billets, because they are not to be rolled further, but billets for the rod mill are not included, since the rods instead are reported. Nail plate, on the other hand, is included. In the following table there is shown the production of rolled iron and of rolled steel in the past eight years, in gross tons. From 1891 to 1903 inclusive rolled steel and rolled iron were not separated in the statistics.

ROLLED MATERIAL, GROSS TONS.

	Iron.	Steel.	Total.
1904	1,760,084	10,253,297	12,013,381
1905	2,059,990	14,780,025	16,840,015
1906	2,186,557	17,401,911	19,588,468
1907	2,200,086	17,664,736	19,864,822
1908	1,238,449	10,589,744	11,828,193
1909	1,760,131	17,935,259	19,644,000
1910	1,740,150	19,881,123	21,621,270
1911	1,460,615	17,578,556	19,039,171

The figures for rolled iron deserve a word of comment. For many years the wrought iron industry was regarded as decadent but the experience of recent years compels an abandonment of that view. As a rule, wrought iron products command higher prices in the market than steel products of similar form and the fact that they are thus purchased cannot be set aside. The last year before the hiatus in the separation of iron from steel in the statistics was 1890, in which year the production of rolled material was as follows, in gross tons:

Iron	2,518,194
Steel	3,504,681
Total	6,022,875

The production of rolled iron had been gaining, but there is reason to believe, in the absence of statistics, that it decreased after 1890. In recent years the production of rolled iron has averaged not far from 2,000,000 tons, and if the 2,518,194 tons produced in 1890 represented the maximum, the wrought iron industry should be regarded rather more as a stationary industry than a strictly decadent one. It may be argued that the industry of 20 or 25 years ago was one of puddling virgin pig iron, whereas the industry now is largely one of working up old material, and in support of this argument the fact can be adduced that in 1911 the total of forge pig reported produced was only 408,941 tons, and a portion of this iron was undoubtedly used in foundry operations, particularly in the production of cast-iron pipe, leaving but little forge pig to contribute to the 1,460,615 tons of rolled iron reported for the year. To this argument it can be rejoined that there is a considerable tonnage of wrought iron produced by manufacturers who definitely follow the practice of puddling pig iron, or a close substitute in the form of cast iron scrap, while the supply of old scrap suitable for busheling and cognate operations is likely to increase rather than decrease, thereby promising a continuance of such operations. With the more general use of the open-hearth steel making processes designed to reduce the need for scrap, the duplex, Talbot, and such processes, it does not appear as certain as it did a few years ago that the basic open-hearth is destined to absorb all the supply of old material not particularly fitted for the foundry cupola.

The rolled steel production of 1911 was 17,578,556 gross tons, which is quite a different quantity from the 23,676,106 tons of steel ingots and castings for the year and which presented the curious spectacle of "the production of steel" exceeding the production of pig iron, for only 23,649,547 tons of pig iron was produced in the year. The item included 646,627 tons of steel castings, leaving the steel ingot production at 23,029,479 tons, from which 17,578,556 tons of rolled steel was produced, 23.6 per cent disappearing, which has been approximately the average in recent years. It is not lost material, since the great bulk passes to the open-hearth furnace and therefore appearing again in the ingot figures.

Without going into minute details, it may be observed that, irrespective of the ups and downs in the total of rolled steel produced in recent years, there has been a great change in the analysis. A smaller proportion than formerly of the total is made up of the heavy products, the lighter products being correspondingly more in evidence. The production of sheets in various forms has increased very strikingly, and particularly for the electrical, automobile and tin plate industries. Wire rods have shown remarkable gains, the rod production being 47 per cent. as great as the rail tonnage in 1906, but 87 per cent as great in 1911.

Detroit Meeting of the American Institute of Chemical Engineers.

The fifth annual meeting of the American Institute of Chemical Engineers will be held in Detroit, Mich., from Wednesday to Saturday, December 4 to 7, 1912. Headquarters will be at the Hotel Cadillac.

The meeting will be opened on the morning of December 4, at the Hotel Cadillac, with an address of welcome by Hon. Homer Warren and a business session, which will be followed by a session starting at 11 a. m. for reading and discussion of the following four papers: Prof. E. E. Ware, on changing rate of setting Portland cement; Mr. Wm. M. Booth, on industrial efficiency and Mr. David L. Davoll, Jr., on technical accounting and chemical control in sugar manufacture. In the afternoon a visit will be paid to the works of Park, Davis & Company.

In the evening of the same day Dr. L. H. Baekeland will deliver his presidential address on the protection of intellectual property in relation to chemical industry. This will be followed by a paper by Prof. A. E. White on availability of blast furnace slag as a material for making brick. This meeting will also be held at the Hotel Cadillac.

During Thursday, December 5, a number of excursions will be made to the plants of the Ford Motor Company, the Acme White Lead & Color Company, and the Pennsylvania Salt Manufacturing Company. Arrangements for automobiles have been made by the Society of Detroit Chemists and the local committee to take members of the Institute and their guests to these plants. In the evening of Thursday a subscription dinner will be held at the Hotel Cadillac.

On Friday morning the members will be taken by special train, leaving Detroit at 8:15, to Ann Arbor, Mich., where the laboratories and buildings of the University of Michigan will be inspected. After luncheon there will be a session devoted to the reading and discussion of the following papers: Prof. M. C. Whitaker, on the chemical engineering laboratory of Columbia University; Prof. Robt. K. Duncan, on industrial fellowships; Dr. G. W. Thompson, on tests on the opacity and hiding power of pigments, and Dr. Edward Gudeman, on composition of glucose and starch sugars.

After this meeting is over a special train will take the members back to Detroit where an evening session will be held at the Hotel Cadillac at 8 p. m. for the reading and discussion of the following papers: Prof. J. H. James, on solvents for acetylene; Chas. A. Newhall, on rotary kiln lining for burning Portland cement, clinker of unusual composition, and S. F. Peckham, on the bituminous rocks of the United States and their use for street surfaces. This will be followed by the final business session.

For Saturday, December 7, visits have been arranged to the following plants: Berry Bros. Ltd.; Detroit Sulphite Fibre Company; Detroit Copper and Brass Rolling Mills, and Michigan Malleable Company.

Dr. L. H. Baekeland is the president of the Institute and Prof. J. C. Olsen, Polytechnic Institute, Brooklyn, N. Y., is the secretary.

The "Destruction of Niagara Falls."

In the editorial "Two Aspects of Conservation" in our International Congress issue of September 12 reference was made to the deplorable cessation of power development at Niagara Falls, due to the international agreement entered into by the United States and Great Britain for the sake of "saving the beauty of the falls."

These remarks have been the subject of some comment in the *Literary Digest* where it is said that "some of us may think that too much of the water is already used for the generation of power."

The New York *Evening Sun* of October 25 replies to this suggestion on its always interesting and instructive editorial page—certainly one of the best editorial pages of New York newspapers—as follows:

"If any do think so, it must be, as we intimated, those of us who have never been there and have to depend on the fables of travelers. Father Hennepin in the seventeenth century described the fall as 'a great and prodigious cadence of water to which the universe does not offer a parallel.' He guessed it to be more than 600 ft. high—about four times the real height. 'The waters,' he wrote, 'which fall from this great precipice do foam and boil in the most astonishing manner, making a noise more terrible than that of thunder. When the wind blows to the south its frightful roaring may be heard for more than fifteen leagues.'

"Another enthusiastic traveler of the same period did not think enough had been made of the scene, and boldly estimated the height at 800 ft. A third was content to describe it vaguely as 'a cataract of frightful height.' Father Hennepin made a remarkable drawing of what he saw, which, as John Tyndall observed, 'shows that serious changes have taken place since his time.' There have been similar serious changes since the development of power began, and they may be as easily accounted for.

"The damage done by the engineers can only be detected by those who have never been near Niagara Falls."

In the issue of November 4th of the New York *Evening Sun* this subject is again taken up editorially. With reference to the remarks of Dr. Louis Bell in our November issue, page 714, on the sociological aspect of electric power distribution over a wide area, these remarks are made by the *Evening Sun*:

"To those who are inclined to dismiss these social considerations as impertinent and still insist on sticking to the single point of the spectacle, it may be retorted that their concern for the scenery is not impressive while they fasten on the power question alone and neglect other points of more moment.

"Only the other day we came across an item in one of the local papers describing a novel project for 'beautifying' the country about the falls. This included the construction of some new inclined railways in the glen, besides 'an aerial tramway across the whirlpool from point to point on the Canadian side, which would soon become famous as a thriller of the first magnitude and an attraction to the million or two of tourists visiting Niagara annually that would rival all other scenic features combined.' This will be followed, no doubt, by further proposals for brightening and prettifying Foster's Flats, one of the beautiful spots that have not as yet been ruined.

"The development of power is insignificant as a destroyer in comparison with the development of 'scenic features' and 'thrillers' for the tripper."

The Western Metallurgical Field.

End of Labor Troubles in Utah and Nevada.

The labor strike which was called by the Western Federation of Miners at Bingham, Utah, and which later spread to Garfield, Utah, and Ely and McGill, Nev., has been practically ended. The strike failed of its ultimate purpose, which was the recognition of the miners' union by the mining and milling companies at the places mentioned. All miners in the Bingham district were called out on strike on the morning of Sept. 18, and the disturbance continued throughout September and most of October. In addition to recognition of the union in dealing with employees, the Federation demanded a flat increase in wages of 50 cents per day.

The Utah Copper Company, the largest company operating at Bingham, steadfastly refused to have any dealings with the Federation, and, together with other companies in the same district, proceeded to import men to work in its mines and mills.

The proceeding was accompanied with a few acts of violence resulting from clashes between the strikers, strike-breakers and deputy sheriffs, and several men on each side were wounded.

For a short time the strike effectually prevented any mining operations, and as a result the large mills of the Utah Copper Company at Garfield, Utah, were forced to suspend operations. The labor disaffection spread also to the smelters of the Garfield Smelting Company, at Garfield, and the International Smelting & Refining Company, at Tooele, Utah, the men at the latter places striking in sympathy with the miners, but not in sufficient number to be effective.

Believing that many of the foreign laborers were coerced and deceived into supporting the strike, the mining companies made every preparation to protect such men as wished to work, and ultimately succeeded in resuming operations, so that by the latter part of October the mines and mills were again running at nearly full capacity. On Nov. 1 the Utah Copper Company voluntarily posted a notice of increase in wages, ranging from 25 cents per day downward, according to class of labor, and effective as long as the price of copper remained at 17 cents per pound or over. In dealing with the strike situation no negotiations were had with the Western Federation of Miners, and in resuming operations no concessions were made to that organization.

In Nevada the situation was rather more critical, being accompanied with several fatalities resulting from conflicts between the strikers and deputy sheriffs. At one time Governor Oddie felt called upon to declare martial law at Ely and McGill, and called out the state police to preserve order. He offered his services as an intermediary between the Nevada Consolidated Copper Company and the strikers, but this was declined by the manager for the company, who announced that the re-employment of men and the rate of pay for labor would be based wholly on efficient service. The company had no objection to its men belonging to the union, but insisted that its operations should not be interfered with by persons outside its employ. The company was forced to suspend mining operations from Oct. 2 to 24, and the concentrator also was idle a part of the time, but by this time the mines and mill are again running at nearly full capacity. A voluntary increase in pay was announced by the company, similar to that in force at Bingham.

A significant incident of the strike was the refusal of the Butte miners to contribute a large sum of money, said to be $28,000, to the support of the Utah and Nevada strike.

Changes at Butte & Superior.

Some changes in the concentrating system at the Butte & Superior zinc concentrator, at Butte, are now under way and probably will be completed early in December. Garfield roughing tables, which have proved so successful in the copper concentrators in Utah and Arizona, are being installed in place of about twenty jigs. The table tailings will be reground and treated in jigs, and the rough concentrates will be retreated on other tables. Experiments have indicated that a better saving will be effected by this change. The capacity of the concentrator is being increased by the construction of a wing in which additional machinery will be placed. An extension of the flotation department also is planned, and the combined changes will raise the capacity of the plant to 2000 tons per day. At present the mill is running only at half capacity, treating ore containing about 16 per cent zinc and yielding tailings of 4 per cent zinc. Mining operations are being extended so that the increased capacity of the mill will be cared for by the time the changes are completed.

Work of the Mason Valley Copper Smelter.

The Mason Valley Mines Company, operating copper mines and a smelter at Thompson, Nev., has made public some figures on the work of the smelter. Forty per cent of the ore now treated comes from the company's own mines, and the balance is custom ore from mines in the district. In the period from Oct. 7 to 14, inclusive, No. 2 furnace smelted 8155 tons of charge, of which 7289 tons were ore. The operation produced 531 tons of matte containing 449,438 lb. copper, equivalent to an annual production of 20,000,000 lb. copper. The daily charge averaged 1019 tons; daily matte production, 66.3 tons, averaging 42.32 per cent copper.

Among the custom shippers to the Mason Valley smelter are the Nevada Douglas, Yerington Malachite, New Yerington, and others of minor importance. In harmony with the action of other copper producing companies, the Mason Valley has announced an increase in wages of 25 cents per day, effective Oct. 1, and in force as long as the present high price of copper prevails.

Jumbo Extension Mill, Nevada.

The Bonnie Clare Mill, south of Goldfield, Nev., is being used to treat the ores from the Jumbo Extension, which adjoins the Goldfield Consolidated. At present the operation consists solely of concentration after crushing with stamps, as it has been demonstrated that this process will recover 80 per cent of the valuable mineral. The mill is equipped with cyaniding machinery which can be used on the tailings whenever necessary. Manager E. S. Van Dyck is authority for the statement that the stamps are crushing an average of 5.7 tons of ore per stamp. The ore has an assay value of from $12 to $42 per ton, averaging about $20. The tailings from concentration assay from $1.20 to $1.60 per ton, and are not considered worth further treatment by cyaniding. Deister sand and slime tables and vanners are used for concentration, and are giving satisfactory results. The present capacity of the plant is only 60 tons per day, but the addition of more tables will bring the capacity up to the expected standard of 100 tons per day.

Company Reports.

Stratton's Independence, Ltd., has issued the fourth annual report on the operation of its mine and mill in the Cripple Creek district, Colorado. The report covers the fiscal year ended June 30, 1912. The following table shows the crude ore treated at the mill:

	Dump Ore, Tons.	Mine Ore, Tons.	Total Tons.	Oz. Gold per Ton	Total Ounces.
Fiscal year	99,378	13,010	112,302	0.155	17,428
Previous year	102,364	7,436	109,800	0.157	17,289

The total recovery amounted to 73.63 per cent of the gross value of the ore, as compared to 71.5 per cent in the previous year. The recovery by concentration amounted to 42.19 per cent and by cyanidation 31.44 per cent, as compared with 43.65 per cent and 27.85 per cent, respectively, in the previous year.

The cost of milling begins with coarse breaking, for which there is a plant at the mine for mine ores and another for dump ores. Following is the cost per ton for the various milling operations:

	Cost per Ton.
Coarse crushing	$0.1694
Fine crushing and concentrating	0.4938
Cyaniding and special chemicals	0.4866
Miscellaneous	0.1211
Total cost	$1.2709

The first-grade concentrate had an average content of 4.34 oz. gold per ton, and the second grade 1.35 oz. per ton. The high-grade concentrate amounted to 82.44 per cent of the total concentrates produced. All concentrates were sold to the smelter, where the treatment cost amounted to $0.137 per ton of crude ore concentrated.

The total cost of all operations, including mining, milling, and treating concentrate was $1.50 per ton of ore treated.

On account of the severe winter of 1911-12 the mill was forced to suspend operations from Dec. 22 to Jan. 17. The expense incurred during this time, and the reduced tonnage of ore treated, increased the expense materially. Deducting this

[illegible] expense the cost of milling for the year was only $1.24 per ton. In March, 1912, the lowest milling cost was reached, when 40,911 tons of ore were treated at a cost of $1.07 per ton. The year has been a successful one on the whole and the outlook for the future is considered good. The directors declared an interim dividend [illegible] payable on November 15.

The Utah Copper Company has issued a report for the third quarter of 1912. Operations were affected by the labor disturbances, as detailed above. The September tonnage fell from over 11,000 tons to about 7000. The total ore treated during the quarter was 1,581,527 tons, of which the Magna plant treated 62 per cent and the Arthur plant 38 per cent. The average assay of the ore was 1.41 per cent copper and the cost per pound of net copper produced was 7.707 cents after making allowances for smelter deductions, but without crediting miscellaneous income. Crediting the latter, the cost was only 7.017 cents.

Excepting during labor disturbances, the Magna plant was in operation full time. The Arthur plant is now remodeled and ready for full production, the thirteenth and last section of the mill having been completed in September. The company announces that it has made arrangements for the purchase of electric power, which will render unnecessary the extension of the steam power plant at the Magna mill.

The report of the **Nevada Hills** company for September has just been issued, from which it appears that during this period the mill handled the largest tonnage in its history. The total ore milled amounted to 3386 tons, of an average gross value of $23.13. The loss in the tailings was $2.02 per ton of ore, leaving a net recovery of $21.11 per ton. The cost of mill was $8.36 per ton, giving a net profit of $12.75 per ton. The total recovery was 91.2 per cent, of which concentration contributed 22.6 per cent and cyaniding 68.6 per cent. The cost of labor per ton of ore milled was $0.93; of marketing the concentrate, $0.64 per ton, and of marketing cyaniding bullion, $0.30 per ton.

Talbot Process for Improving Soundness in Ingots.

In an editorial in our last issue we referred to the new Talbot process for improving the soundness of steel ingots as made known at the last meeting of the (British) Iron and Steel Institute. Further details of the process were given by Mr. **Benjamin Talbot** himself at a special informal meeting held on November 7 in New York City under the auspices of the Iron and Steel Section of the American Institute of Mining Engineers. Mr. Charles Kirchhoff presided and Mr. Bradley Stoughton acted as secretary.

After some introductory remarks on the problem of segregation and cavities in steel ingots, and on the effect of the size of the ingot, and the unfavorable effect which large ladle heats of 100 tons have, Mr. Talbot took up the importance of the deoxidizer needed to eliminate blow-holes.

"Sound ingots as regards the elimination of blow-holes are produced by means of the well-known powerful deoxidizers, aluminium, silicon, and ferrotitanium. All the deoxidizers have the same effect, when used in the necessary varying quantities to produce this. They all produce solid steel except for the large central cavity. They all diminish segregation. In my experience I have found with well-made steel that an addition of 2 oz. to the ton of aluminium is equal to 0.25 per cent of added silicon, and an addition of 0.10 per cent of metallic titanium in the form of ferrotitanium. These additions will all produce the same characteristic central pipe, and if they are used this piped portion should be discarded in each case."

It occurred to Mr. Talbot "that if we were to use a deoxidizer such as aluminium to eliminate blow-holes in the outer envelope of the ingot and then reduce the area of the ingot or the top portion, while the center was liquid, the pipe would not [illegible] and a sound [illegible] be found in the [illegible] of the squeezed ingot.

"In [illegible] compressed ingot, which was cut longitudinally through its center, I came across an interesting discovery. I found that whenever an ingot was compressed while its center was liquid, no segregation formed in the center of the upper part as is usual, but that it was driven to the internal face of the solid envelope in fairly regular percentage over the entire length of the liquid area. The solid outer envelope is the normal steel of the heat and is about 3 in. The carbon in this portion in this case is from 0.65 to 0.70; the carbon in the harder portion next this is from 0.75 to 0.80, and in the center about 0.50. The sulphur and phosphorus also vary in these strata, but as the phosphorus is low in this steel it was not of sufficient amount to be considered.

"In ingots compressed while their center is liquid without the use of a deoxidizer, I find that the center shrinkage cavity is not formed, but that the blow-holes, which are found in the outer envelope, are not obliterated and can be traced into the rail. For this reason I prefer to use a deoxidizer so as not to have any surface blow-holes, which tend to give spongy rails.

"The method of procedure is as follows: An ingot of at least 20 x 24 in. in cross section is used; 2 oz. of aluminium to the ton of steel is added to the ingot as it is being poured. Aluminium is preferred because of its low cost and its low melting-point. It causes a perfectly solid outer envelope to be formed, and solidifies the metal earlier than if no deoxidizer were used. The ingot therefore can be stripped earlier, and it is then put into the soaking pit to allow the envelope to become thicker, and at the same time have a proper temperature upon its surface for compression. A 20 x 24 in. ingot is reduced to about 18 x 18 in., and it is then returned to the soaking-pit for a proper heating and solidifying of the mass. After this has been accomplished, it is rolled down into a bloom, cropped and passed to the rail-mill. The rail produced has the same characteristic formation as the squeezed ingot, viz., a hard working-face, harder ring at back of this and softer center.

"It is the question of this new formation that we manufacturers have to discuss with railroad engineers and metallurgists."

There was a long and animated discussion in which Messrs. H. M. Howe, H. D. Hibbard, A. A. Stevenson, E. F. Kenney, P. H. Dudley, Charles Kirchhoff, W. C. Cushing, M. H. Wickhorst, Bradley Stoughton, and W. R. Walker participated. The letter stated that the United States Steel Corporation would make a trial of the process.

Mr. Talbot is the inventor of the Talbot continuous open-hearth steel process which he developed while connected with the Pencoyd Iron Works in Philadelphia.

Meeting of the American Iron & Steel Institute.

The third general meeting of the American Iron and Steel Institute was held in Pittsburgh, Pa., on Friday, October 25th. The attendance was 375. That is practically one-half of the membership.

Judge E. H. Gary, in his presidential address, delivered in the morning, spoke of Pittsburgh as a steel center and of the most gratifying conditions and the era of prosperity now existing in the steel industry. "These conditions have not resulted from the application of political policies or efforts, but exist in spite of them." After pointing out the importance of the technical problems which were to be discussed at the meeting he referred to more important subjects and questions which must be solved and which involve the welfare of everyone. "The thought I would leave with you is that there is no way of permanently settling any great question involving the welfare of human kind except on the basis of right and justice.

Position, welfare, influence, laws are helpless as a means of establishing a rule for human conduct unless supported by principles of justice and righteousness." The following four papers were then presented during the morning session:

The Buyer from the Manufacturer's Standpoint, by John L. Haines.

Technical Training for Steel Salesmen, by James M. Camp.

The Use of Mayari Iron in Foundry Mixtures, by Quincy Bent.

The Manufacture of Ordnance at the Bethlehem Steel Works, by E. C. Grace.

After a buffet luncheon had been served the following papers were presented during the afternoon session:

Coal Mine Ventilation in the Connellsville Coke Region, by Austin King.

Recent Developments in the Preparation of Iron Ores, by J. W. H. Hamilton.

Microscopic Analysis of Steel Sheets, by C. Arthur White.

Electric Power Production and Distribution in Steel Works, by Stewart C. Coey.

The dinner in the evening was exceedingly enjoyable. A feature of it was an exceedingly interesting moving picture show "from iron mine to molder," by Rogers, Brown & Company.

The Spring meeting will be held in New York City as is the custom of the Institute. For the Autumn meeting it is possible that Birmingham, Ala., may be selected to pay a tribute to the developments of iron and steel manufacture in the South.

The Iron and Steel Market.

The conduct of the iron and steel market in November has been phenomenal. It has gained rather than lost strength, and at a period in the year when to gain strength has hitherto always meant to establish the character of business in the coming year as particularly good. The improvement has, moreover, been in the face of a sweeping Democratic victory at the quadrennial election, with assurance of radical tariff revision next summer. The steel trade, it should be noted, does not greatly fear tariff revision for its direct effect. It fears, rather, the depressing effect upon general business which radical downward revision of the tariff is quite generally held to promise.

The ordinary observer regards the demand for steel as exceptionally heavy for, not accustomed to quantitative conceptions, he measures demand simply in terms of capacity, failing to allow for the accepted fact that if demand is but slightly under the productive capacity all buyers pursue the most conservative course, buying only from hand to mouth and making no forward commitments, while if demand slightly exceeds capacity the buyer piles orders upon the mills and observing that they are filled up buys farther and farther ahead. A small difference in the actual consumptive requirements develops a very great difference in the amount of business which is offered to the mills. It needs only that consumptive requirements slightly exceed productive capacity, or sometimes the mere fear on the part of buyers that they will not be able to secure desired deliveries, to fill mills with business many months ahead. Sometimes the business on books proves substantial, and sometimes it proves quite otherwise. The condition of mills being filled with business far ahead does not establish it as a fact that demand is abnormally heavy, for it is merely the relation between productive capacity and demand which produces the condition. For half a century or more, up to 1907, the production of pig iron in the United States doubled on an average once in ten years, and the same statement can be made as to rolled iron and steel for the shorter period in which complete statistics have been gathered. Adopting this rule and using the figures of 1905-6-7 as a basis, a tonnage is found for the present time quite in excess of the productive capacity. To denominate the present demand as exceptional is to assert that it is known the rule of increase broke down a few years ago, which would be absurd since it is much more rational to judge the rule by the actual developments. On this basis the inference is rather that the increase in productive capacity has been abnormally small in very recent years. So much was said in 1908, when demand was very light and the trade was committed to a heavy new construction program, about capacity having outrun demand, requiring a period of years for a readjustment to be effected, that the memory remains while it is not recognized that the period of years has really elapsed. In 1906 the production of pig iron was 25,300,000 gross tons and the production of finished rolled iron and steel 19,600,000 gross tons, and the rule of doubling in ten years would require a production 41.6 per cent. greater in 1911, or 35,800,000 tons of pig iron and 27,800,000 tons of rolled iron and steel. More than a year after the middle of 1911, however, the average rate of pig iron production is not more than 32,000,000 tons, with rolled iron and steel being produced at the rate of about 26,000,000 tons, while the demand apparently outruns the capacity. Such increase in production as has occurred is not all in material available for the domestic market, for exports in 1906 were 1,300,000 tons, which with a 41.6 per cent increase would be 1,850,000 tons for this year, when the actual rate of export is 3,000,000 tons.

The reasonable inference, therefore, is not that the present demand is exceptional, but that productive capacity has failed to increase in accordance with requirements.

It should be observed, however, that in the past demand has not increased uniformly, and it is only by averaging periods of years that a law can be developed. In studying the present conditions attention should therefore be directed to all sources from which information can be obtained to aid in forming a judgment.

One special definite cause of heavier consumptive demand at this time is that railroad expenditures have greatly increased, based partly upon the very favorable earnings in the past few months and partly upon the certainty of heavy earnings at this time and until the end of the crop moving period. In purchases of material for specific purposes in November railroad buying was by far the most prominent. There was little of buying against large structural operations, but a great deal of contracting by jobbers and also by ordinary manufacturing consumers.

Such business proves trustworthy if general business conditions continue good, and not otherwise.

On Tuesday, November 19, one of the Cleveland ore firms announced prices on Lake Superior ores for the season of 1913, stating at the same time that it had effected some sales. The prices thus announced have been accepted by ore sellers as the regular basis. They are as follows, for ore delivered Lake Erie docks, 55 per cent iron content, natural state, with 10 per cent moisture, for Bessemer ores, and 51.50 per cent iron content, natural state, with 12 per cent moisture, for non-Bessemer ores:

Old range Bessemer	$4.40
Old range non-Bessemer	3.60
Mesabi Bessemer	4.15
Mesabi non-Bessemer	3.40

These prices are precisely 10 cents below the 1911 schedule, and 65 cents in the case of Bessemer and 55 cents in the case of non-Bessemer, above the nominal prices for 1912, the market having been rather unsteady during the year. The 1911 schedule, which is so closely approached, was identical with that of 1908 and 1909, but 50 cents below that for 1907 and 1910.

The early opening of the selling season is an evidence of strength in the general iron and steel market and is with one exception the earliest for at least a quarter century.

Pig Iron.

Pig iron prices trended upwards during November, but much less so than in October. Sales of foundry grades were lighter,

out were quite heavy in the case of Bessemer and basic in the Central West, chiefly for delivery in the early months of next year. Connellsville coke ruled at about $4 a ton for prompt shipment, while on contract for first half the market advanced to $3.25 and $3.50, according to grade. The advances in coke and ore absorb the greater part of the advance in pig iron which has occurred in this entire movement, and furnaces will perhaps endeavor to secure further advances in pig iron, based upon the advance in ore for next season, but the relation between ore and pig iron prices is frequently lost. It is significant, for instance, that the 1912 ore prices were announced last March, with reductions of 65 to 75 cents, whereas it was at that very time that pig iron began the real upward movement. The market is now quotable as follows: Bessemer, $17.25; basic, $16.50; No. 2 foundry, $17.25 to $17.50; forge, $16.75 to $17; malleable, $17 to $17.25, f.o.b. valley furnaces, 90 cents higher delivered Pittsburgh; No. 2X foundry, delivered Philadelphia, $18.25 to $18.50; No. 2 foundry, f.o.b. Chicago furnaces, $18. No. 2 foundry, Birmingham, $14 to $14.50.

Steel.

There are no regular sellers of steel billets and sheet bars, mills being well sold up for months, and a number of finishing mills appear to be left with an insufficient amount of steel under contract for the first quarter. The market can only be quoted approximately, prices being largely nominal: Bessemer billets, $27; sheet bars, $27.50; open-hearth billets, $28; sheet bars, $28.50; rods, $30, f.o.b. maker's mill, Pittsburgh or Youngstown.

Finished Steel.

There are two markets, one at which the large mills will accept business for far forward delivery and the other a market made by smaller independent mills which can make earlier deliveries. Regular prices for forward delivery are given below, prices being f.o.b. Pittsburgh unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill except Colorado.

Plates, tank quality, 1.50 cents.

Shapes, 1.50 cents.

Steel bars, 1.40 cents.

Common iron bars, 1.65 to 1.75 cents, Pittsburgh; delivered Philadelphia, 1.67½ to 1.75 cents; f.o.b. Chicago, 1.60 to 1.65 cents.

Steel hoops, 1.50 cents.

Sheets, blue annealed, 10 gage, 1.65 to 1.75 cents; black, 28 gage, 2.25 to 2.35 cents; galvanized, 28 gage, 3.40 to 3.50 cents; painted corrugated, 28 gage, 2.45 cents; galvanized, 3.45 cents.

Tin plates, $3.60 for 100-pound cokes.

Merchant steel pipe, ¾ to 3-in. jobbers' carloads, 70 per cent off list.

Steel boiler tubes, 3½ to 4½-in., 72 per cent off list.

Standard railroad spikes, 1.85 to 1.90 cents.

Button head structural rivets, 2.10 cents; cone head boiler rivets, 2.20 cents.

The Non-Ferrous Metal Market.

The non-ferrous metal market has been rather quiet since our last report, with slightly receding prices for some of the metals, notably lead and spelter. Demand has been only moderate and there has been an evident desire on the part of producers to make prices which would force sales.

Copper.—The market has been dull, and while the principal agencies have maintained their prices, it is known that considerable business in electrolytic has been effected by shading the quoted prices. The latest available quotations are 17½ @ 17¾ cents for Lake copper and 17.35@17.45 cents for electrolytic.

Tin.—The foreign market remained firm early in November, but weakened about the middle of the month, due to large Straits shipments. Domestic sellers have made inducements to effect sales, and November tin is quoted at 50 cents.

Lead.—Although the A. S. & R. Co. has maintained its price of 5.10 cents, business has been done at lower figures owing to offerings of western lead at lower prices. The market has been rather dull and weak. New York quotations are 4.62½@4.67½ cents, with St. Louis at 4.47½@4.52½ cents.

Spelter.—Prices have tended to decline slightly on account of the dullness of the market, but there was an upward tendency about the middle of November, particularly for spelter for early delivery. The latest quotations are 7.25@7.30 cents, St. Louis, and 7.40@7.45 cents, New York.

Other Metals.—Prices for aluminium are not quite so firm, quotations at New York being about 27 cents per lb. The antimony market is quiet but firm, quotations ranging from 9¼ to 10⅜ cents for various grades. Business in quicksilver has been good with steady prices at New York. The metal is quoted at $42 per flask of 75 lb. at New York, and $41.50 for domestic orders at San Francisco and $39 for shipment to foreign countries.

CORRESPONDENCE.

Troostite.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—I regret that the article on troostite in your April issue had hitherto escaped my attention. Since its writer has most distinctly misread my paper[1] which he quotes, it seems desirable if you will kindly grant me a little space, to correct his error, which will then enable me to show that the views I then stated are in accordance with all the latest accepted theory. The fact is that in my paper I was endeavoring to show that Boynton had made certain errors, and Boynton has since admitted that his conclusions were erroneous. I was guilty of indulging in a gentle sarcasm, and it was this which was misunderstood by Bullens, as it was by Benedicks in 1905.[2] In the case of Benedicks one might plead that the paper was not in his language.

I actually gave my opinnion (p. 486, loc. cit.) as follows: that troostite is "a mixture, fairly intimate, but not so much so as is solution, of ferrite or cementite with a solid solution of the two. In the case of medium carbon steels . . . troostite would probably consist of such a mixture of ferrite and solid solution." The gentle sarcasm was in my remark on p. 485: "The writer fails to see why it (troostite) should be β iron rather than γ." I will now fill this remark in so that it can surely no longer remain ambiguous. It should then read: "All of Boynton's arguments would apply equally well to prove that troostite is γ iron, as to prove that it is β iron; this would be so obviously absurd that neither Boynton nor anyone else would for a moment advance such a theory."

Troostite is such an important constituent to all metallographers who "acquired the habit" of metallography before the innovations in nomenclature that I feel this is sufficient apology for again opening this very live subject.

F. ROGERS.

Sheffield, England.

"Exothermic" Steel.

To the Editor of Metallurgical and Chemical Engineering:

SIR: Mr. Amsler in your November issue says in his letter that: "If any critic will submit a better chemical explanation of the matter than the one given it will be thankfully acknowledged;" also that: "Constructive criticism will be welcomed." I accept both invitations.

In the original article on "Exothermic Steel" in your September issue it is stated that: "A quantity of iron ore and flux was mixed in a No. 4 graphite crucible, which was then placed in an ordinary cast-iron 'cannon-ball' stove and well

(1) Iron and Steel Institute Journal, 1905, 1, pp 484-486
(2) Ibid., 1905, 2, p. 363.

packed in coal. After about fifty minutes the crucible was removed to find the molten iron separated out under a cover of fluid vitreous slag." The flux referred to was feldspar, bauxite and limestone with no carbon, and the experiment is supposed to prove the *reducing* action of this flux. I have already characterized this supposition as unbelievable. I prefer to believe that the carbon of the graphite crucible containing the mixture is one reducing agent which Mr. Amsler has ignored and the white-hot carbon monoxide atmosphere in which the crucible is immersed (it was "well packed in coal") provides another reducing agent which must not be overlooked. These two supply all the reducing action necessary to explain the reduction of the iron ore without assuming in regard to feldspar flux that it acts reducingly and exothermally like free aluminium.

Since "matte" is a melted sulphide, mostly of copper and iron, Mr. Amsler should not use this term for an entirely different product. He should at once abandon the term "matte" in connection with his furnace, because he has no right to use it as he does. Let me suggest as a more appropriate name, "smelting" furnace, and for the product, "sponge." These may not be acceptable to Mr. Amsler, but he owes it to his standing as a metallurgist to drop at once his misuse of the term "matte."

As to the product, it certainly looks like "good stuff"; so good that it is a pity it should have had such a misnomer as "Exothermic Steel" tagged on to it and also a greater pity that it should have been heralded by such a sorry apology for a scientific explanation of its reason to exist. I herewith offer the only one which at present appears to me as reasonable, namely, that good ore is used and pure fuel and that the cleansing influence of a rather expensive but very efficient feldspar flux is responsible for the rest. I believe that a light, fluid, clean slag, capable of absorbing and holding the various metallic oxides and compounds which usually contaminate the fluid steel may have very striking effects on the quality of the metal. I think that any open-hearth steel would be improved by using some feldspar flux just as it is known to be improved by using fluorspar.

If anyone has better explanations than those offered above I shall be interested to hear them.

Jos. W. Richards.
Lehigh University.

To the Editor of Metallurgical and Chemical Engineering

Sir:—In Vol. X, No. 9, page 559, of this journal W. O. Amsler, D.Sc., published an article on "exothermic steel" which was very interesting and suggestive. In the article it was stated that even tungstic acid could be reduced to metallic tungsten by means of this process, whereby a great saving of power might be obtained.

The present writer has had the opportunity of testing this statement on a laboratory scale, and although the result was negative, it may be of interest to relate the test since negative results are, in a way, very instructive and a report of the same may also lead to a very valuable discussion, in as much as it may be shown why a result is a negative one.

According to the chemical equation for iron, as given in the article mentioned, a corresponding equation for WO_3 was drawn up and the following mixture prepared, using a tungsten ore containing 72 per cent of WO_3 and some calcium oxide, silicate, etc., which was all considered in making up the charge.

The charge consisted of:

Ore	100 lb.
Feldspar (potassium)	132 lb.
Bauxite	60 lb.
Lime	10 lb.
Carbon	4 lb.
Iron	6 lb.

This would give approximately 60 lb. of alloy containing 80 per cent of tungsten, taking losses into account.

The mixture was gradually charged into a well burnt laboratory electric furnace with one floating and one bottom electrode, fed with alternating current in the usual way. A thick "sticky" slag was obtained, which proved to be very vitreous after cooling, showing the appearance of an impure glass.

Altogether 210 kw-hours were required to melt down the whole charge, and judging from the "boiling" the reaction was expected to take place. When the "boil" subsided, after the whole of the charge had been melted, the mass was left to "soak" for some time, allowing the temperature to rise considerably.

The top layer of slag was drawn off and the remainder was left in the furnace to cool.

After cooling, the mass was broken out and examined. Altogether about 280 lb. of slag was obtained, and a cake of fused semi-metallic substance, weighing 59 lb. This was found to contain on an average 50 per cent of metallic tungsten, while the slag contained 9.9 per cent of W.

In the whole 56.6 lb. of W were charged into the furnace; 29.5 lb. were recovered as a semi-metal while the rest, or 27.1 lb., were lost in the slag, showing an actual loss of 48.2 per cent.

It shall not be said on account of this meagre result that the method is a fallacy; it is quite possible that if the process is more carefully studied a more promising result may be obtained, and it should be of great interest to have the test criticised, and modifications suggested. This much shall be said, however:

The amount of feldspar and also of bauxite required, according to the equation, is very considerable and will of necessity create a large amount of slag, which is bound to take up a considerable quantity of metal under all conditions, even if the actual analysis shows a fairly low figure of percentage.

Furthermore, the heat expected to develop from the reaction itself is not realized in practice; if one has to spend as much as 210 kw-hours to obtain about 30 lb. of tungsten, very little is gained in this respect, more so as it was fully evident that still much more heat would have been required to cause a complete reaction and separation, if such were possible.

The cost of especially the feldspar, and also to some extent of the pure ground bauxite, is far too high to compensate for this, when it is considered that the ordinary reaction with carbon (coke or graphite) only as a reducing agent hardly requires more, but rather less power and produces infinitely less slag.

It will, however, be of interest to criticise the statement from a chemical point of view. The author of the article mentioned (page 559) writes the formula for the iron oxide reaction as follows:

$$Fe_2O_3 + 2K\,Al_2\,Si_3O_8 + 2Al_2O\,(O\,H)_4 + CaO =$$
$$2Fe + 4\,Al_2O_3\,6SiO_2\,2KOH\,CaO + 3H_2O$$

In the first place, the expression 2KOH is evidently an error, as it is not likely that this highly vitreous slag should contain any H_2O; it should rather read $K_2O + 4H_2O$. This, of course, may be only an oversight in writing it down.

The formula given for the feldspar, however, is open to a more serious consideration. The definition of a true feldspar, as given in all handbooks and as borne out by chemical reasoning, contains one monoxide, one alumina and two to six molecules of SiO_2. Consequently the expression for feldspar in the above equation should read $(K_2O\ Al_2O_3\ 6SiO_2)$ or by halving it as shown in the equation, it should be:

$$2(K\,Al\,Si_3O_8) \text{ and not } 2Al_2, \text{ etc.}$$

If we now write the equation out in this way

$$Fe_2O_3 + 2K\,Al\,Si_3O_8 + 2Al_2O(OH)_4 + CaO$$

we find that there is no binder for the 3O in the Fe_2O_3. This has only been provided for in the original equation by writing

the feldspar $KAlSi_3O_8$ thus introduced, two extra atoms of Al which, of course, would form AlO_3 or really present in practice.

If, however, the ordinary potassium-feldspar and the bauxite only are to be used, it seems that a reduction of the ore can only be effected through the carbon, which the author states "could" be introduced. In this case the spar and the bauxite are only slag-forming ballasts, and this would, of course, account for the unsatisfactory result obtained when the writer attempted to reduce the wolfram ore. The addition of metallic aluminium is not mentioned in the article.

It was fully evident that the reaction did not proceed of its own account after it had been heated to the ignition point by means of the electric arc, as would have been the case if free aluminium had been present.

The writer wishes to repeat, however, that there is plenty of room for explanations, which he hopes will be forthcoming, and that a single trial like the one described should not be considered conclusive; in the interest of general knowledge, however, the matter ought to be cleared up.

Luton, Beds, England [illegible]

To the Editor of the Metallurgical & Chemical Engineering:

Sir: The time in which to reply to Professor Richards' recent and more courteous letter is too short to go into the matter as fully as I would like.

The object of the experiment of the number 4 graphite crucible was not, as Professor Richards says, to prove the reducing action of the flux so much as to prove the exothermic nature of the reaction. That carbon plays an important part in the reduction has not been and is not denied, but on the contrary it is considered an essential element. That packing of the graphite crucible in coal will produce a reducing atmosphere should be evident to any metallurgist without having it pointed out to him. However, the reducing atmosphere will not reduce ore and limestone under these conditions without the flux. Neither is it possible to melt steel scrap in the same reducing atmosphere. In fact, none of the ingredients of the charge taken by itself can be so melted. Yet the addition of the feldspar, bauxite and limestone to the ore will reduce the ore and produce a liquid steel which will pour as readily as water if it is not left in the stove too long after the reduction. If the metal is not poured promptly it will freeze in the bottom of the crucible. This same experiment has been made many times and has also been made with 50 per cent ferrotungsten.

I would suggest that Professor Richards make these experiments to satisfy himself. The actual demonstration is much more convincing than any amount of argument no matter how erudite. Whether the flux actually reduces the ore or whether it takes it up in a solution of vitreous slag so that the carbon, silicon or aluminium can act differently than they do in the usual processes, I will not undertake to say, but it undoubtedly does produce a reducing condition that is different and it undoubtedly is accompanied by a rise of temperature.

There seems to be considerable misapprehension as to the amount of flux required to produce the desired results. The amount of feldspar used is generally about one, and bauxite ½ per cent of the weight of the ore. There must be a sufficient amount of carbon present to accomplish the reduction, as the amount of reduction accomplished by the flux is probably small. The chemical explanation made in the article was intended to apply only to that portion of the reduction not accomplished by the carbon.

In regard to the quantity of flux to be used, the figures given are for the practical operation on a large scale. For laboratory experiments, especially with the No. 4 graphite crucible, the quantity required is from ten to fifteen times that given.

It is immaterial to me what the product of the stack furnace is called so long as Prof. Richards and I understand each other when it comes to [illegible] "sponge" or hammered [illegible] a refined metal in a state of loose physical structure, whereas matte is a partially refined metal, a term applied, it is true, at present almost exclusively to copper, but I see no reason why it should not be broadened. The product of this stack furnace is undoubtedly a partially refined product, as it carries the metal and all slag, including any sulphur, copper, or other impurity that may get into the furnace and that is not taken out by the blast.

Experimenters must not expect the exothermic reaction to be as violent as that of the "thermit process." When the temperature of the charge reaches the critical stage the reaction will increase the temperature above that of the surrounding fire or furnace, but upon withdrawal of the support of this outside source of heat so that the temperature falls by radiation or otherwise the reaction will cease.

I have not yet had time to go fully into the rather long letter of Mr. Joh. Harden, but it seems that the amount of feldspar and bauxite used was nearly a hundred times too much.

Pittsburgh, Pa. WALTER O. AMSLER.

Proposed Code of Ethics of the American Institute of Chemical Engineers.

To the Editor of Metallurgical & Chemical Engineering:

Sir: I enclose an "Open Letter" to those who would impose a "Code of Ethics" on the American Institute of Chemical Engineers. Since the question at issue is of general interest, you may find it expedient to publish these views.

Dear Sirs: The fact that other engineering societies have adopted a "Code of Ethics" is not a satisfactory reason why the Institute of Chemical Engineers should adopt one. They may have made a bad mistake in adopting a code, and it would then be no credit to us to follow their example. Let us make our own mistakes, if we are going to make any, and not simply repeat the mistakes of others.

The Institute of Chemical Engineers was intended to be select, to contain only men of prominence and accomplishment in their profession. Its foundation was partly a protest against the indiscriminate character of the membership of the American Chemical Society, and because membership in that society conferred no distinction. Such being the high character of the membership of the Institute, it is unfitting and ill-advised to formulate "rules of conduct" for them, as if they were tyros in the art of being "an honest man and a gentleman."

The adoption of such a code would distinctly lower the dignity and distinction of membership in the Institute. It is, by assumption, unnecessary, because we elect as members only men who by action and achievement have shown themselves to be distinguished gentlemen. To prescribe to such, for example, that they shall "be guided by the highest principles of honor," is as unnecessary as it is silly and ridiculous; indeed, it is a gratuitous insult to every member of the Institute.

I do not hesitate to say, that if any member of the Institute has lost self-respect to such extent that he feels that he, himself, needs such a prescription as that just quoted, to keep him in the path of honor and rectitude, then he should be thoughtful enough to resign from the Institute before he brings discredit upon it. The Institute is not a reformatory.

Neither do I hesitate to say that any member who recognizes that he himself does not need such a prescription, but still would impose it on the Institute "for the benefit of his weaker brothers," is an unmitigated cad, and unfit to direct or influence the proceedings of the Institute.

I sincerely hope that the whole proposition will be voted "down and out" for good; every member who votes for it stultifies himself.

The Effect of High Carbon on the Quality of Charcoal Iron

A Paper Presented at the Cleveland Meeting of the American Institute of Mining Engineers by J. E. Johnson, Jr.

Charcoal iron is quantitatively so unimportant compared with coke iron that its qualitative importance for many industrial purposes is entirely unknown to many coke furnacemen.

To explain this qualitative importance and explain some of the factors that affect the quality are the objects of this paper.

The advent of coke iron, which transformed the whole iron industry commercially, left intact a limited production of char-

FIG. 1.—TESTING ARRANGEMENT.

coal iron in the East and South, which has been conducted always on the basis of high cost and high quality, with correspondingly high selling price. In the Northwest, particularly in the Lake Superior district, the development has been along totally different lines, for which the close proximity of the great iron ore deposits and the great forests of that region were responsible.

When the great white pine forests were removed there were left behind large areas of hardwood and hemlock, to which little attention was paid in the prosperous years of the white pine industry. But when the latter declined the demand for lumber and the presence of lumbermen, probably more skilled than any others in the world, caused the gradual introduction of these woods into commercial use.

It was a matter of ancient knowledge that hardwood made an excellent charcoal, and to utilize the cordwood left after the saw logs were removed by converting it into charcoal and using it to produce pig iron, with ore from the adjacent mines, was an obvious step.

In some cases the establishment of the furnace occurred independently of the lumbermen through common knowledge in the iron trade of the favorable conditions for a supply of raw material.

This outline is not intended to be historic in any other sense than as describing broadly the causes which produced a certain condition.

The abundant supply of both iron ore and hardwood made feasible the establishment of larger plants with greater outputs than prevailed at the Southern and Eastern ones, where there was generally a never-ending, life-and-death struggle for sufficient raw materials of both kinds to keep the operation alive.

Parallel with this development came that of the recovery of the by-products in the production of charcoal. First, methyl alcohol, commonly known as wood alcohol, and, secondarily, acetate of lime, from which are produced acetic acid and acetone. The varnish industry absorbed enormous quantities of both wood alcohol and acetone and this consumption steadily grew. This caused the construction of wood carbonizing plants, of which the so-called by-products became the principal object, and the charcoal the real by-product.

In the palmy days, before the repeal of the tax on grain alcohol used industrially, and before competition had lowered the price of the acetate, the by-products would pay for the wood from which they came, its carbonization and their recovery, leaving the charcoal literally as a by-product.

In order to turn this charcoal into money, some market for it must be had, and the easiest market was to build a furnace and run it virtually as an adjunct to the chemical plant. In this way many plants were run by men who had an exceedingly limited knowledge of the iron business and less of the quality of the iron they produced, and as, in their efforts to learn, they had to draw their information principally from the coke trade, the shrine at which they worshiped was high production.

The larger units led, naturally, to the introduction of economies which were not worth while in the similar plants of the East and South, notably the hot blast, from the use of which the coke trade found such great benefits in increasing production and decreasing fuel economy. It was natural that the charcoal producers should assume that the same conditions would hold with them to the same extent.

The iron was sold for what it would bring, and as the fuel cost was relatively low it could naturally be sold at exceedingly

FIG. 2.—TYPICAL SPOTTED IRON.

low prices compared with Southern and Eastern charcoal iron, where the wood by-product industry had never taken root successfully, in conjunction with the iron business.

Commercial pressure during successive depressions in the iron business took advantage of these conditions and of the

actual decline in the quality of Lake Superior charcoal iron and forced its price down to a figure ridiculously low, compared with that of the Southern and Eastern irons.

In the summer of 1910 when the Lake Superior Iron & Chemical Company of New York was organized and took over six plants in the Lake Superior region, these conditions had prevailed so long that while the price of warm-blast Southern and Eastern irons ranged from $23 to $33 a ton at the furnace, with a ready sale for all that could be made, Lake Superior charcoal irons of far superior analysis, were a drug on the market at from $14 to $16 per ton.

Mr. Wm. Wilkins, the General Superintendent of the Iron Department of the above-named company, set himself the problem of finding the reason for this discrepancy in price, and of removing the cause if it was in the actual value of the iron. An investigation to find the conditions affecting quality was, therefore, undertaken at the Ashland plant, of which I was at that time appointed manager.

An investigation along the lines of consumption showed that different irons have different characters totally independent of their analyses. I do not for a moment intend to imply that the accepted opinions concerning the control of carbon condition by silicon, fluidity by phosphorus and chilling qualities by manganese are not in a general way correct. I do intend, however, to declare that the presence or absence of these elements *alone* will not account for all, scarcely for a half of the facts which have long been known, not to us, but to those who used high-grade irons for special purposes.

Investigation showed that there were foundries using chemistry not only for silicons and sulphurs, but also for carbon determinations and advanced work of that kind. We found that such foundries had proved by the most irrefutable tests that they could take a certain iron of a given analysis and produce certain results with it in chill, depth and uniform interlacing of chill with gray, hardness and toughness of chill combined, with corresponding resistance to abrasion, freedom from pits and from local failures of various kinds. With another iron of the same analysis they could not produce these results at all.

This was true not only of charcoal iron as compared with

FIG. 3.—WHITE PORTION OF FIG. 2.—70 DIAMETERS.

coke, but of one charcoal iron and another. We found that some carwheel manufacturers knew how to produce and did produce regularly, when they could sell them, wheels that would give service of many thousand miles in excess of that given by other wheels of their own make, made to be sold to people who insisted on having low price rather than quality. We were shown pieces of castings made with these different mixtures which contained ocular evidence sufficient to convince the most obstinate that there were physical variations not dependent on similarity of analyses in any recognized element.

As a result of these conditions there have grown up branches of the foundry trade forming a relatively small fraction of the whole, but of enormous commercial importance nevertheless, whose whole product is based on their being able to secure and to use irons which give them qualities beyond those obtainable from the ordinary coke foundry irons. These are particularly

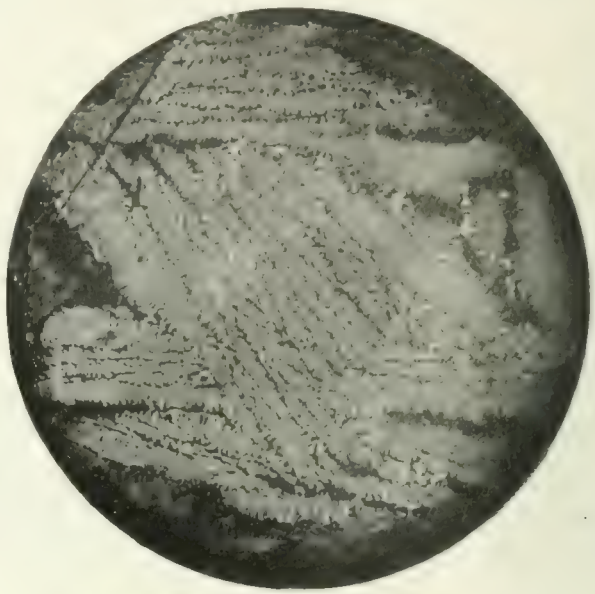

FIG. 4.—WHITE PORTION OF FIG. 2.—38 DIAMETERS.

the manufacturers of chilled rolls and of chilled car wheels, though there is a growing demand for irons of high strength and close grain, without great chilling qualities, for many purposes, notably gas engine cylinders and the like.

The production of chilled car wheels in this country is enormous. The steel wheel has by no means filled the promise implied in the name of "steel." The first cost is very high and the durability is not great, even with the four expensive turnings which it receives during the course of its life. There is no difficulty whatever in demonstrating that more miles of wheel service under a given load may be obtained for a dollar with chilled cast iron wheels made of suitable irons properly mixed than can be obtained from a steel wheel, and in fact probably 90 per cent of the freight traffic of the country is carried on chilled car wheels to-day and will continue to be for many years to come. This branch of the business alone is of such vast commercial importance as to justify industrially and financially the great expense which has been incurred by the present investigation.

When the technical investigation was started I had no idea but that within a year or so we would have solved the problems presented to us, of which we had no detailed knowledge at that time.

This investigation has now been in progress for two years. In that time we have proven to be true many things which we did not believe, and have proven to be untrue many things of which we were firmly convinced, but we do not yet consider that we are within measurable distance of the final solution of the great problem—why one iron should be so different from another of the same analysis.

But experiments on the furnaces themselves, covering the widest possible range at all consistent with commercial operation, have indicated to us methods whereby the quality of the iron may be vastly improved from the state of things described in the introduction.

Some of our investigations on the iron itself have yielded partial results, and careful study of the relation between

furnace operation and quality of iron has enabled us to determine furnace lines and some of the operating conditions to give the desired results.

Practically all the plants have been rebuilt to embody the results of the investigation to date.

The investigation is still going on, and in its course we have come upon what seems to me the explanation of a phenomenon which has puzzled many—iron with a white or close spot in the center.

The difficulty of the investigation is one that is hard to overestimate, and even more difficult to explain to the satisfaction

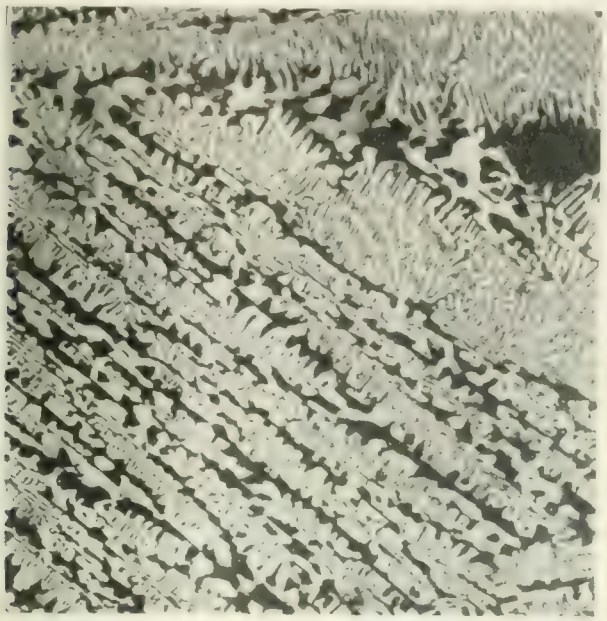

FIG. 5.—WHITE PORTION OF FIG. 2—100 DIAMETERS

of those familiar only with the coke iron trade.

I had been in the latter trade practically all my life and there was no one more deeply immersed in its traditions than myself.

I had taken some part in the development of the now accepted belief that soft steel, hard steel, white iron and foundry iron were members of a single series of iron-carbon alloys of increasing carbon contents, that silicon controlled the condition of the carbon, and that the chemical analysis of pig iron for the ordinary elements of silicon, sulphur, phosphorus and manganese, gave the final decisive word as to the character of the iron.

The logical ultimate deduction from this theory was that given the analysis, the character of the iron was established and virtually no attention need be paid to the fuel used in its production or any other consideration affecting its origin.

It is a matter of common knowledge that the only essential difference in the conditions when manufacturing iron with charcoal instead of coke consists in the fact that the charcoal is so free from sulphur that much less calcarious, and, therefore more fusible, slags can be used without danger of introducing sulphur into the iron. Any coke furnaceman, knowing this to be the sole essential difference between the two kinds of iron, and convinced, as most of them are, of the close correspondence between analysis and character, may well find it impossible to believe that such difference can exist, not only in strength but in appearance and structure between irons of similar analysis as we actually find in daily practice. That such a widely variant series of products can exist outside the knowledge of coke furnacemen is explained by the fact that we could run charcoal furnaces with slags similar to theirs and produce a line of products approximately similar to theirs in all respects, but by lowering the lime content of the slag we can bring into effect a vast series of varying conditions, which are masked, if not altogether obliterated, by basic slags and the high temperatures necessary to fuse them. These conditions are impossible for coke iron, because the resultant rise in its sulphur contents would ruin it. I am moved to lay stress on this point of variations in quality not dependent on variations in analysis by the clear recollection that my own point of view when I first entered the charcoal iron field was that above outlined and probably is that of most furnacemen to-day.

It is true that I had noted with much interest certain variations in coke iron of the same analysis dependent on varying furnace conditions, and I had very definite ideas as to the type of fracture that was good and what was bad, as affected by these conditions.

These views, however, were distinctly subordinate to the broad view of analysis control of iron, of which I was a strong advocate.

When we were confronted with the overwhelming commercial fact that the Southern and Eastern irons sold for from 50 to 100 per cent more than we could obtain for our product, the natural and obvious thing to do was to claim ignorance and prejudice on the part of the foundrymen, and poor salesmanship on the part of the agents, because any tyro could compare the analyses of our iron with that of the Southern and Eastern irons and see that ours were the better.

Gradually, however, the indefatigable efforts of Mr. Wilkins brought us into contact with foundrymen who obviously knew their business at least as thoroughly in both practice and theory

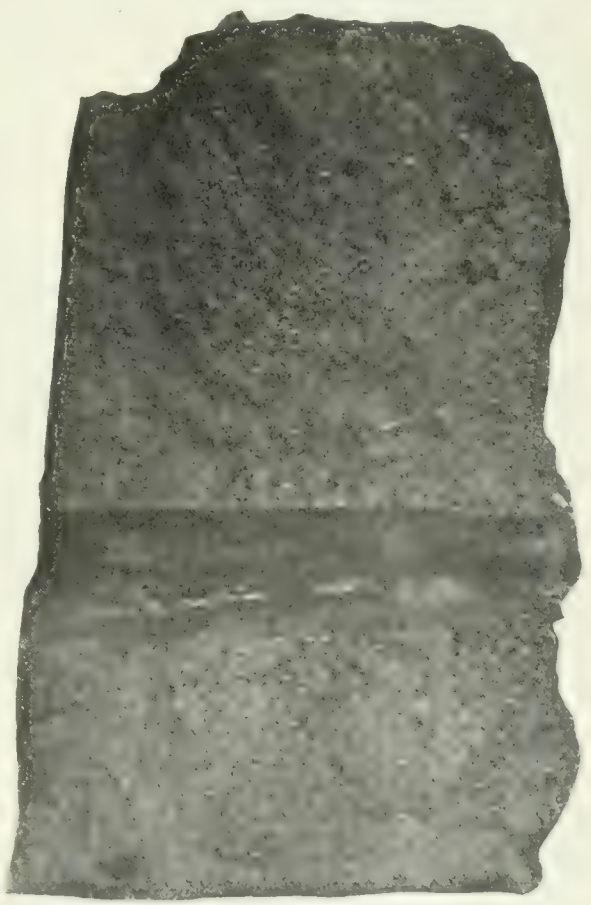

FIG. 6.—LOW 4 SPOTTED IRON. VERY HIGH CLEAVAGE

as we knew ours, and they gradually convinced us by the hard logic of irrefutable physical facts that the difference in price corresponded to a difference in quality and in ignorance, as we had supposed, but that we, and not they, were the possessors of the surplus stock of ignorance.

Experience with these Lake Superior charcoal irons taken in

[illegible] with frequent analyses had led to the [illegible] card, which is given herewith:

Grade	Silicon Average	Chill Depth	Manganese Grade.	Manganese Malleable Grade.
AA Scotch	3.00% and over			
A Scotch	2.75			
B Scotch	2.50			
C Scotch	2.25			
No. 1 Soft	2.00		0.70% or over	Under 0.70%
No. 1 Special	1.75		0.70 or over	Under 0.70
No. 1 Foundry	1.50		0.70 or over	Under 0.70
No. 2 Low	1.25		0.70 or over	Under 0.70
No. 2 High	1.00	No chill	0.70 or over	Under 0.70
No. 3 Low	0.80	Feather	0.60 or over	Under 0.60
No. 3 Med.	0.65	[illegible] to [illegible]"	0.55 or over	Under 0.55
No. 3 High	0.55	[illegible]" to [illegible]"	0.50 or over	Under 0.50
No. 4 Low	0.45	[illegible]" to 1 1/4"	0.45 or over	Under 0.45
No. 4 High	0.35	1 1/4" to 2"	0.40 or over	Under 0.40
No. 5 Low	0.30	Near white	0.35 or over	Under 0.35
No. 5 High	0.20	White, spot		
[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Near White	0.10	Clear white		

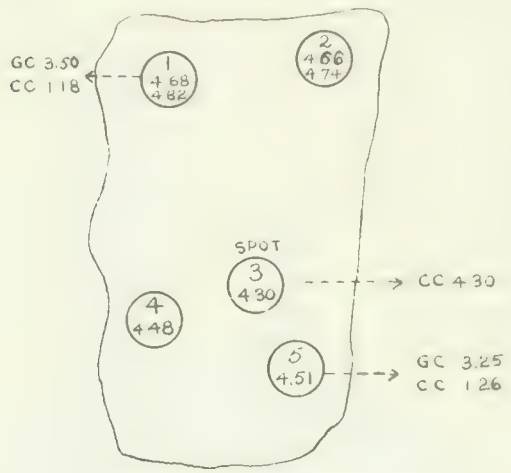

FIG. 7.—SHOWING POINTS OF ANALYSIS.

Fig. 7.

ANALYSIS.

No.	Si. Per Cent.	Mn. Per Cent.	P. Per Cent.	S. Per Cent.	T.C. Per Cent.	G.C. Per Cent.	C.C. Per Cent.
1	0.32	0.32	0.118	0.022	4.68 4.82	3.5	1.18
2					4.66 4.74		
3					4.30		1.30
4					4.48		
5					4.51	3.25	1.26

It will be noticed that there is an assigned depth of chill for each analysis. To gauge the chilling qualities of an iron it is the custom to have a heavy block of cast iron planed on one side, which forms a portion of one side of the pig mold for one pig in every third bed. The chill on this chill block is the one referred to in the grading card given above.

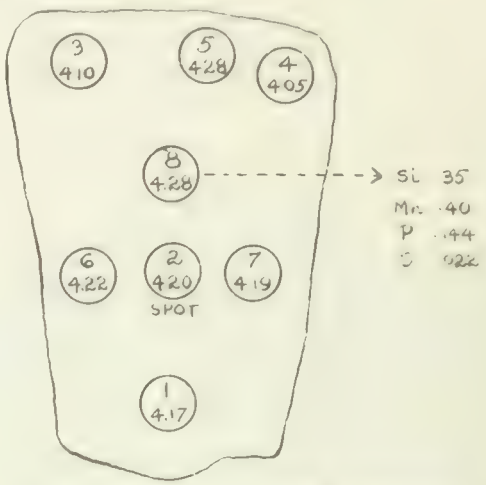
The grading card was based on the three principal lines of consumption of these irons, as follows:

First. Straight foundry work, especially that of the better class where strength and density of grain were required, but not chilling qualities.

Second. The production of chilled casting, principally car-wheels and chilled rolls where manganese was supposed to be beneficial.

Third. The production of malleable cast iron, in which low manganese is generally specified.

It will be noticed that the silicon limits from one grade to another are very narrow and that the grades run much higher than No. 1. This is probably, to some extent, because the small quantity of sulphur present does not neutralize much of the effect of the silicon, so that the latter reaches the limit of its effect much earlier than in irons with higher sulphur, so consequently in some of its qualities to No. 1 soft coke iron, with 3.25 per cent silicon.



[illegible] ANALYSIS

Fig. 8.

ANALYSIS.

No.	T.C. Per Cent.	Si. Per Cent.	Mn. Per Cent.	P. Per Cent.	S. Per Cent.
[illegible]	[illegible]				
[illegible]	4.20				
[illegible]	4.10				
[illegible]	[illegible]				
[illegible]	4.28				
[illegible]	4.22				
[illegible]	[illegible]				
[illegible]	4.28	[illegible]	0.40	0.144	0.022

For the foundry trade silicon is needed for scrap-carrying purposes and the like, as with coke irons, and irons with more silicon than No. 1 soft are graded as Scotch irons.

Because of the rapid variation in grade, with small variation in silicon, the practice was early established of taking a sample for silicon analysis from every third bed and grading the iron by the results of these silicon determinations. Two manganese determinations were also made on each cast. This grading card was established several years ago, and, while it has recently been amplified, the silicon limits of the grades are practically unchanged.

When we began our investigation one of the great difficulties with which we had to contend was to find out what was good iron and what was bad. Was a strong iron necessarily a good iron, or a weak iron necessarily a bad one? It will seem inconceivable, but it took a year and one-half before we found anyone to give us a definite answer to this question. It was finally answered by the superintendent of the carwheel foundry of a large railroad system, who, by his practical knowledge of the business, and by physical tests of the irons he purchased, combined with judicious mixing and excellent foundry practice, produced wheels that stood an average of ninety-five thousand miles in service, as against an average of from thirty to forty-five thousand miles for the wheels of the ordinarily commercial wheel foundries.

This gentleman assured us that for his purpose a good iron was a strong one, and a strong one a good one. The standard of strength with him was a 2-in. square bar, broken transversely on centers 12 in. apart. If the strength for a given grade was up to certain limits and the chill of a certain depth, the iron was good. If not, the iron was undesirable for his purposes and was rejected.

This condition of complete ignorance as to what to investigate caused the investigation to take shape very slowly. We

started at once with pyrometric observation of the temperature of the running iron and cinder, and bought a small transverse testing machine capable of breaking a 1¼-in. round bar on 12-in. centers, the standard recommended by the American Foundrymen's Association. We cast four bars on end in green sand molds with iron dipped directly from the runner, at each cast, and broke these on the testing machine. We believed, however, that we should have a record of the stress-strain diagram of the test bars and we accordingly bought, a little later, an autographic machine, designed and made by Tinius Olsen & Co., of Philadelphia, for this purpose. This machine draws a line on a 5-in. square chart, the abscissae of the line showing the stress applied, and the ordinates the corresponding deflection, right up to the point of rupture. After certain minor changes were made this machine was easy to manipulate and the quality of the iron was soon found to have a decided bearing on the character of the curves produced.

There were two well-established traditions in the business when the investigation was begun. One was that an iron with a white chilled spot in the center of the pig, which is some-

FIG. 9.—END OF PIG SHOWN IN FIG. 6 SHOWING LAMINATION. UNETCHED. 70 DIAMETERS.

times produced, was weak and utterly worthless for the manufacture of chilled car wheels, or in any other purpose requiring a strong, tough chill. This is known as "spotted iron."

Second, that an iron was made under certain conditions in which the grain was exceedingly close, verging slowly into a chill of greater intensity than the silicon contents of the iron would explain, and that this was a very strong, tough iron, particularly suited for cylinder castings on account of its high strength and exceedingly close grain, taking a high finish. In consequence it was given an individual name, "special cylinder iron," and saved for certain customers to whom it was particularly valuable, though it is a lamentable fact they formerly got it without paying anything like an adequate price for it. This iron is produced as the result of certain unusual furnace conditions, and may have any silicon contents from 0.5 per cent to 2 per cent.

The first positive results of the investigation were to prove that this special cylinder iron was far stronger than normal, and that, on the other hand, the spotted iron was far weaker, thereby confirming thoroughly the traditions of the practical men whom it had been the custom to deride.

At the expense of much time and money, Mr. Wilkins secured samples of the best brands of Southern and Eastern irons, from which remelts were made in order to determine their strength, also complete chemical analysis for comparison

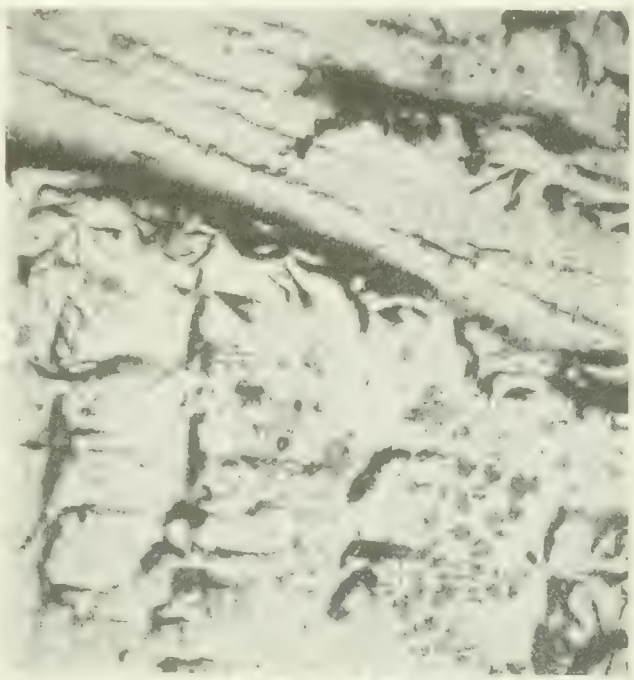


FIG. 10.—CORNER OF PIG SHOWN IN FIG. 6 SHOWING LAMINATION. UNETCHED. 70 DIAMETERS.

with our own. Gradually it developed that we needed something more, and a microscopic outfit and polishing apparatus were added. Subsequently it became a conviction in the minds

FIG. 11.—CORNER OF PIG SHOWN IN FIG. 6 SHOWING LAMINATION. ETCHED. 70 DIAMETERS.

of all, particularly in that of Mr. Wilkins, that reliable carbon determinations were a necessity.

It is well known to all who have tried to get carbon determinations of pig iron that there is no greater bugbear in the laboratory, and the attempt to obtain accurate ones lasted for a

year before we had discovered all the conditions necessary to get reliable results. We soon found, however, that one carbon determination per day was not enough, and we then added an extra man in the laboratory and began to get total and graphitic carbons on every cast in addition to the six silicon and two manganese determinations for each cast. We added also a phosphorus and sulphur determination for each cast, and by means of the latter destroyed the beautiful delusion that good charcoal iron ordinarily contains about 0.01 per cent sulphur, since accurate determinations show nearly all of it to contain from 0.015 per cent to 0.020 per cent, even when made from the best of ores, and very much higher if there is more than a trace of sulphur in the ore.

More than a year ago we put in a crucible furnace for making crucible remelts of irons, to determine the effect of

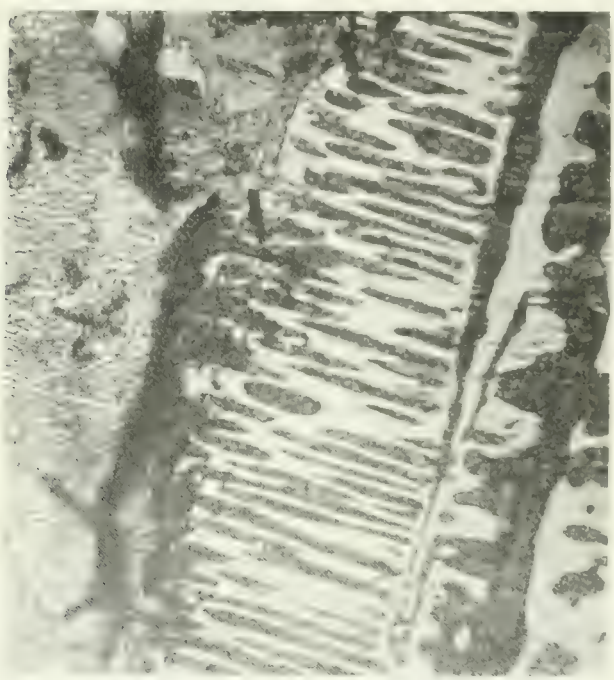

FIG. 12.—CORNER OF FIG. 9 SHOWN IN FIG. 9 SHOWING LAMINATION MORE DEEPLY. 450 DIAMETERS.

remelting on our own iron and to obtain results comparative with those of others which are generally made on remelted iron. If the test is to represent the actual quality of the iron crucible remelts must be used to prevent oxidation, contamination with sulphur, and the like.

We at first made these remelts only on very unusual irons of our own or on irons from outside sources, and used the 1¼-in. round test bar, but later, finding what great dependence the foundrymen placed on the 2-in. square bar, broken transversely on 12-in. centers, we began making remelts of every cast of iron suitable for chilling purposes—that is, everything below the No. 1 grades, making both 2-in. and 1-in. square test bars.*

In order to utilize all this information, the iron is all piled by grades, but the portion of a given pile which comes from a given cast is bulkheaded off from the portion on either side of it and marked with a tag, giving the date and hour of the cast and the silicon and manganese of that portion of the pile. The daily furnace reports carry the ordinary information contained in a daily report, and in addition, the carbon determinations, at least one slag analysis, the temperature of the running iron and cinder, the breaking strength of 1¼-in. round bars poured from the cast, and the breaking strength of the remelt bars on the chilling grades of iron. By means of this system we know the exact iron which goes out on each order, and when we get an order for exactly the same kind of iron, we can take our records and locate it with little or no difficulty. In this way we are able to direct the various grades and kinds of iron to the fields of consumption to which they are best adapted. This system involves extensive records and a considerable amount of clerical work, but gives results so satisfactory to consumers that we find it well worth while.

The opinion gradually took shape in my mind that the spotted iron, the normal iron and the special cylinder iron were the members of a continuous series of increasing quality, and that if we could find out the cause of the spotted iron and the proper method of prevention, we would have at least part of the problem solved. This view has gradually been confirmed by the progress of the investigation, and we have further found some of the factors which tend to increase the strength of the iron and move it from the normal to the special cylinder quality.

We do not feel that we have yet reached the complete solution of these matters in such a degree as would make

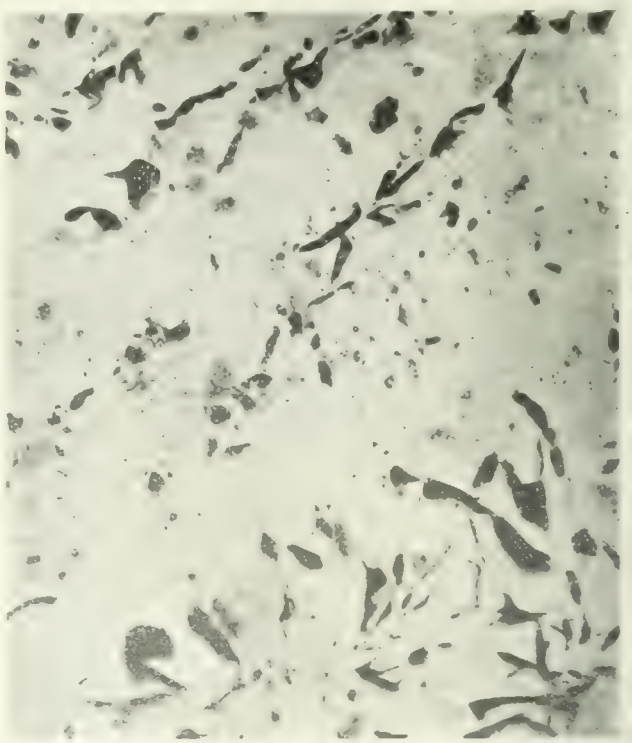

FIG. 13.—CORNER OF FIG. 2 SHOWN IN FIG. 2 RELATIVELY SLIGHT LAMINATION COMPARED WITH FIG. 9 OF THE NEXT HEAT. 100 DIAMETERS.

their publication safe and desirable, but we think we have succeeded in finding the cause of the spotted iron and in connecting up its analysis and physical qualities and assigning to it its proper place on the iron-carbon diagram.

Fig. 2 is a photograph of a representative piece of spotted iron. It shows the white spot in the center with two rudimentary branches extending toward the upper corners of the pig. When I first gave thorough consideration to this kind of iron it seemed to me that the location of the white spot

*The transverse strength of a good 1¼-in. round test bar on twelve-inch centers will sometimes go as high as 30,000 pounds, and to break these and at the same time avoid the expense of buying a testing machine of this capacity, we rigged up a removable girder over our track scale to carry a screw and ratchet lever strong enough for the purpose. The screw carries at its lower end a knife-edge, which is guided by a square shank to prevent its turning. The test bar is placed on a pair of knife-edges, twelve inches apart, resting on transverse I beams inserted between the main I beam of the scale platform. Guide pins run through guides mounted on the girder which carries the screw, and through guide holes in the plate carrying the bottom knife-edges. These locate the bottom knife-edges accurately under the center of the top knife-edge in both directions. The stress is put on the bar by the hand lever, as shown, and the load on the bar weighed on the scale beam. With very little practice it is possible to get results accurate within one hundred pounds or less. As the apparatus serves the purpose of an expensive testing machine very satisfactorily for those who have a relatively small amount of such work to do, it is thought that its description may not be amiss.

indicated that it was a segregation product, and I had analyses made of the gray portion outside and of the white spot, with the result of finding that the total carbon was about ½ per cent higher in the former than in the latter, but no material variation in the other elements, certainly none in either the silicon or the manganese, which would account for the internal chill in spite of its being slowly cooled.

I was informed by experts in the metallurgy of iron that the ordinary explanation of this phenomenon was that the

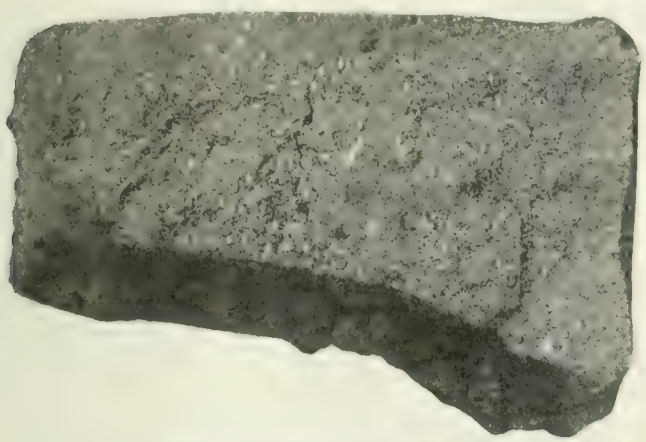

FIG. 14.—HIGH NO. 3 IRON WITH TENDENCY TO SPOT.

T.C.	4.46

center of the pig was still liquid when the exterior had solidified, and that the expansion which accompanies the evolution of graphite was not permitted to take place on account of the contraction of the solid envelope on the liquid interior, but as iron of all grades cools under precisely these conditions and only a small percentage of it is spotted, this explanation could not be regarded as satisfactory.

Gradually investigation and observation developed the fact that the irons in the low and high No. 4 grades were most apt to be spotted, but that a tendency to spot was sometimes shown in softer grades, notably the No. 3 iron, even though the pig itself might not show any trace of spot. For instance, the test pins in these grades might have a very small spot, even when the pig had none at all.

We have repeatedly heard the term "high cleavage" used in connection with the Lake Superior charcoal irons by experienced users, and we had at one time considered that this was part of their unreasonable prejudice against this iron, but we gradually found that certain irons which had this tendency to spot showed a degree of lamination where they were chilled, or partly chilled, that was almost beyond belief. In the corners of some pigs there could be seen with the naked eye alternate layers, perfectly white and solid gray, the white leaves being no thicker than ordinary writing paper, the gray perhaps twice as thick. It was obvious that such iron must break along the faces of these leaves of white, and that the term "high cleavage" expressed its quality more accurately than any other equally simple term. Stereoscopic photographs (which, unfortunately, cannot be reproduced in the printed paper) will be shown to all interested, which illustrate the characteristics of the fracture of this iron more accurately than any amount of description.

Observation gradually brought out the fact that while the special cylinder irons showed a tendency to chill much more than their silicon contents would lead one to expect, these irons with a tendency to spot, even though not actually spotted, showed a chill much lower than their analysis would warrant, and more than a year ago we began the practice of marking such iron with a distinctive mark and forbidding its shipment to manufacturers of chilled car wheels or any similar article, because we found the testing machine confirmed the ocular judgment that these irons were of the general nature of spotted iron, and therefore, very weak. We had photomicrographs made of the irons shown in Fig. 1, particularly of the spotted portions which are reproduced in Figs. 3, 4 and 5. It is obvious that the masses of detached plates of which these areas are made up simply abut against one another and are not in any way interlaced, so that a very low intensity of stress will cause cleavage along the face of one or the other of them. We finally recognized the structure as shown by the photographs to be that of eutectic cast iron of 4.30 per cent carbon, as shown by Fig. 118, page 175, of Goerens' "Introduction to Metallurgy."

Simultaneously with the microscopic examination of a specimen of this iron we repeated our earlier determinations of the carbon in the light of the most recent developments in those determinations, with a view of corroborating our earlier results, and we obtained the results shown on the accompanying chart. It then became evident that our earlier opinion that this was a segregation product was correct and that the white chilled spot was the eutectic of 4.30 per cent carbon, which had gone to the same relative position in the pig as that in which we find the segregated portion of a steel ingot and for the same reason; that both had remained molten on account of their low freezing temperature after all the other portions of the mass were solidified.

From this point the investigation and this description of it naturally divides into two parts. First, what are the causes

FIG. 15.—CORNER OF PIG SHOWN IN FIG. 14 ETCHED 70 DIAMETERS

of this action? Second, how far does the action extend and how serious are its effects in industrial work?

Without any desire, or ability, to make this a purely scientific matter, it was necessary to align the results of the investigation with the established iron-carbon diagram in order to check our results, and the portion of the article from this point to the end of the fifth paragraph on page 786 seems to us the explanation of the observed facts on this basis. From that point on the conclusions based upon those facts are given. My

[illegible] knowledge of the iron-carbon diagram prevents the former portion from being particularly technical, but it may be undesirably so, for those who desire conclusions only, and all such may omit the former portion without other loss than the danger of being misled by erroneous conclusions in the latter section. As these are based principally on observation and but little on deduction, this danger is not serious.

It so happened that our first investigation of carbon contents in various portions of the face of the pig was made not on the iron shown in Fig. 2, but on that shown in Fig. 6. These carbon determinations and their location are shown by Fig. 7. It will be observed that the carbons in the gray portion are all much higher than that in the spot, and being unfamiliar with the interpretation of the iron-carbon diagram we first assumed that it was only hyper-eutectic irons which could thus segregate and that the phenomenon was one confined to the right hand branch of the iron-carbon liquid diagram.

This error was fostered by the fact that we had a suspicion that the high carbon irons were the bad ones. We came gradually to realize, however, that this explanation was not valid and that segregation of eutectic could take place in hypo-eutectic irons as well as in hyper-eutectic, so that any interpretation of the facts based on the former assumption only was wrong.

It is obvious that irons on the right hand side of the eutectic point throw out only graphite in cooling down to the eutectic freezing point, so that the ground mass of the whole pig, exclusive of the small proportion of graphite so thrown out is eutectic at the time of final solidification. But the center is free of these particles of this graphite because it has remained liquid so much longer as to give them a chance to separate out by gravity into the portion above the spot. Therefore, when the iron cools down below the eutectic freezing point, the portion around the spot contains many particles of graphite which probably act as foci to cause other graphite to precipitate out of the mass from the solid condition. The

[illegible]

center is without these foci, and is, moreover, under compression from the contraction of the previously solidified exterior, which prevents the expansion necessary for the evolution of graphite, therefore, no graphite forms.

The iron shown in Fig. 2 was subsequently analyzed for [illegible] as shown in Fig. 8. It will be seen that the spot contains the highest carbon, except the gray portion immediately above it, which is only slightly higher. The [illegible] in carbon than the spot. In these portions solidification has obviously taken place, first, as austenite with a lower carbon content and correspondingly higher freezing-point than the

[illegible]

eutectic. These portions had no deposition of foci of graphite while liquid to induce the precipitation of more graphite during cooling in the solid state, but had the ability to form a solid structure of austinite (undoubtedly immeshing pools of eutectic therein) which would solidify earlier and therefore be in better position to exert pressure during contraction on the central liquid portion than if all froze at the same temperature. In other words, the austenite is capable of making, and does make, a continuous structure with a freezing point higher than the eutectic, whereas the graphite in the hyper-eutectic irons cannot form any continuous structure and does not affect the freezing temperature of the principal portion of the exterior mass.

We have here also the obvious action that when there is carbon in excess of the eutectic ratio the excess falls out and the whole mass, except these isolated flakes of primary graphite, is composed of eutectic. In the hypo-eutectic irons, on the other hand, it is obvious that less eutectic can be formed according as the carbon content of the whole is further below the eutectic ratio.

In the hyper-eutectic irons the isolated particles of graphite can exercise but little influence on the formation of the plates of eutectic whose shape, size and utter lack of interlacing accounts for the poor physical qualities of this kind of iron. In the hypo-eutectic irons, on the other hand, a skeleton of austenite called by Professor Howe primaustenoid, forms first, and being relatively solid through being well below its freezing point at the time of the freezing of the eutectic, can prevent the formation of large plates of the latter, which, if formed, act like gigantic cleavage planes on the mass as a whole. The further the carbon content of the whole is below the eutectic ratio, the earlier must be the freezing of the austenite and the greater its quantity before the formation of the eutectic can begin. Therefore, the more powerful will it be in preventing the formation of the huge plates of eutectic when the eutectic freezing point is reached, while the quantity of the

latter which can form is diminished at a still more rapid rate.

If this explanation be correct it is obvious that the cleavage condition, visible to the naked eye, must be vastly more extensive in a hyper-eutectic spotted iron than in a hypo-eutectic one, and that it must extend to the very exterior of the pig in the former and be more and more restricted to the center as the carbon is lower in the latter. These conditions we find in fact to exist. The fracture of the iron at the exterior of the pig, shown in Fig. 2, is not particularly high cleavage, whereas the iron shown in Fig. 6 is of most peculiar appearance. There are close-grained spots scattered all over its face, not perfectly white, but visible upon close examination to the naked eye as plates of solid white alternating with layers of gray; in other words, the most accentuated condition of cleavage we could find. This cleavage condition is usually manifested particularly in the upper corners of the pig, and from one of these corners of this pig we took a specimen which was polished and photographed without etching, so as to show the lamination and orientation of the graphite. This is shown in Figs.

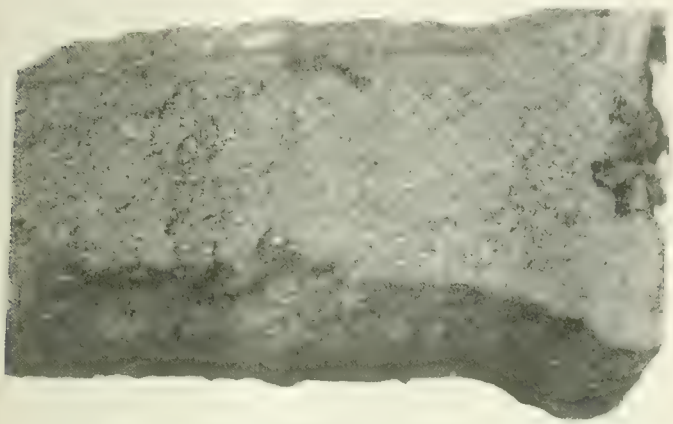

FIG. 18.—LOW NO. 2 IRON.

9 and 10. The same sample, etched and at the same magnification, is shown in Fig. 11 and under higher magnification in Fig. 12.

In order to prove if a contrast existed we took a similar corner of the pig shown in Fig. 2 and prepared a specimen in the same way. The result is shown in Fig. 13, unetched.

It will be seen at a glance that the laminated condition is much less and the graphite much less oriented in this specimen than in the other one. This being a hypo-eutectic iron, the portion which froze first was austenite, and there were only puddles of eutectic left to make the few long flakes of this material shown. The graphite is fine, scattered and nodular, an indication of its being secondary graphite, while some of the graphite in Figs. 9 and 10 is large and in relatively long flakes, an indication of its being primary.

Allusion has been made to irons which had a tendency to spot without being actually spotted. These irons usually occur in the No. 3 grades. In addition to these we have noticed irons in the No. 2 and even softer grades, with a close spot in the center, surrounded by more open-grained material.

After we had this clue it was relatively easy to find from the results of the test bars that those casts with this fracture were likely to be below the normal strength for their grades, and by examining the upper corner of the pig we were able, in some cases, to detect slight traces of cleavage. We accordingly prepared a specimen from the upper corner of a pig of high 3 and photographed it without etching.

The original pig is shown in Fig. 14, and the micro-photograph of the specimen in Fig. 15. The cleavage planes and the orientation of the rows of graphite show a structure obviously identical with that in Figs. 9 and 10, though slightly less pronounced. This also was a hyper-eutectic iron, as shown by its analysis. The same structure, etched, is shown in Fig. 16.

If the theory outlined above is correct it is obvious some of the graphite in the hyper-eutectic irons is primary, and if so, it will naturally occur in relatively large flakes quite thin in relation to their length and breadth. Moreover, the graphite, not having any continuity of structure, is obviously at the mercy of the eutectic crystals, and when the latter begin to form they can push the graphite flakes around so that while the long axes of the flakes may not be aligned, the flakes as a

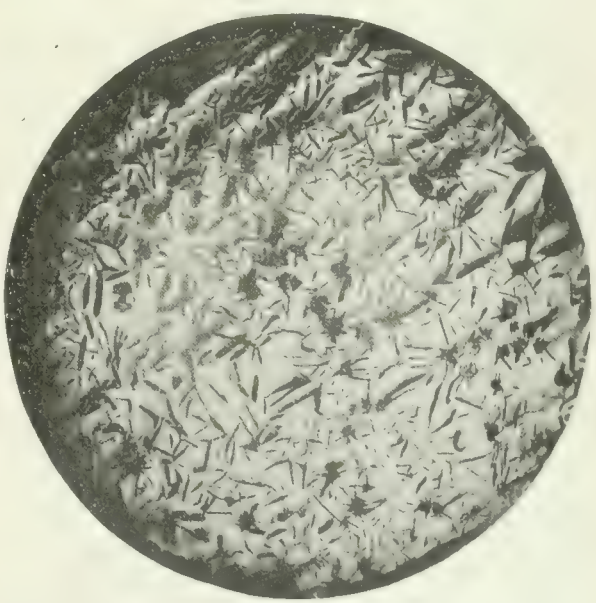

FIG. 19.—CORNER OF PIG SHOWN IN FIG. 18. NOTE ORIENTATION OF GRAPHITE. UNETCHED. 38 DIAMETERS.

body are arranged in windrows. This condition is plainly evident in Figs. 9, 10, 11, 12, 15 and 16. Fig. 17 is the same as Fig. 14 at a higher magnification, and shows the same condition within its limited field.

It will be noticed that the plates of eutectic shown in Figs. 15, 16 and 17 are considerably more broken up than the similar areas in Figs. 3 and 4. This I take to be the result of the greater silicon content of pig shown in Fig 14 than that shown in Fig. 2, and is reflected in the solid gray fracture of the

latter as compared with the partially white fracture of the former. The effect of silicon is obviously to break up these plates of eutectic into pearlite and cementite, and then, in some cases, to break the latter up into pearlite and graphite. If this be true, then we should have an orientation of the graphite even in irons so high in silicon as to have left scarcely any traces of the original eutectic.

In order to prove or disprove this hypothesis we took a pig of low No. 2, shown in Fig. 18, in the corners of which we found faint indications of cleavage and prepared a specimen

FIG. 20.—CORNER OF PIG SHOWN IN FIG. 18. ETCHED. 100 DIAMETERS.

from its upper corner, which is shown in its unetched condition under low magnification in Fig. 19. The orientation of the graphite from the upper left to the lower right-hand corner is plainly visible. The same specimen etched is shown under a higher magnification in Fig. 20. In this the long windrows of white dots represent all that is left of the cementite, which once composed part of the eutectic plates. The darker rows of graphite flakes are plainly observable between the windrows of white dots. The carbon determinations taken in the face of this pig are shown in Fig. 18.

We seem justified in believing that this was a hyper-eutectic iron in which the silicon had forced down the eutectic point to about 4 per cent instead of 4.30 per cent. The fact that the segregated spot is lower than the rest of the pig in carbon and the presence of the residual plates of eutectic in the corners, which we have seen are most likely in hyper-eutectic irons, is our justification for this belief.

In order to confirm the above theory more fully, we took one normal white iron containing 3.71 per cent carbon, made under ordinary working conditions for white iron, and a white iron made on a very cold furnace, containing only 3.3 per cent carbon, and prepared specimens from each. Photomicrographs of these are shown in Figs. 21 and 22. The former will be seen to have a well developed pine-tree structure at the point photographed, and at other points in the same sample this structure was even more markedly developed. In the low carbon iron it will be seen that there is no sign of the pine-tree structure, and careful search of the whole field of the specimen reveals scarcely any of it, thus proving that when the iron is far enough below the eutectic ratio this structure cannot form to any appreciable extent.

The fact that eutectic can form in iron practically free from silicon, as low in carbon as 3.71 per cent and practically without segregation (the carbon in the center being 3.72 per cent as against 3.71 per cent at the side), may be thought contradictory to the theory here advanced. Examination of this iron under the microscope seems to indicate that there probably was the early formation of austenite which had its effect in orienting the flat crystals of eutectic as they formed, so that they are much more interlaced than any higher carbon white areas. It would seem as though the original austenitic structure had been overwhelmed by the crystals of eutectic freezing from the pools of that material enclosed by the austenite network.

While these investigations were in progress Mr. R. W. Durrett, manager of the Newberry plant of this company, determined some of the conditions controlling the carbon contents of pig iron and was enabled to produce irons of very low carbon, in some cases as low as 3.3 per cent. We happen to have here a specimen of this iron, with the analysis shown. The closest examination by eye failed to show any traces of cleavage and there was not the slightest indication of spotting. Specimens of the iron were prepared for the microscope and photographs of the results under different manifications are shown in Figs. 23, 24 and 25. The irregular polygons of primaustenoid are quite plainly visible, but there is not the slightest sign of any residual of the eutectic. This iron is evidently so far below the eutectic ratio that the heavy network of primaustenoid completely overwhelms the attempt of the eutectic to crystallize into flat plates. This is the easier, as but very little of the eutectic can form with this low carbon content. The structure of primaustenoid is one which we have learned to associate with high strength, and there is no doubt that a test of this iron would show a high result, though we have not such a test available.

We have endeavored to obtain specimens of coke iron containing such white spots in the center, but so far without success. My recollection is quite distinct, however, that these irons are not infrequent in basic practice. We shall take the first opportunity to determine whether the same conditions hold in those irons as those here shown.

Allusion has been made to the fact that irons, either spotted or with a tendency to spot, are commonly deficient in chilling

FIG. 21.—HINKLE REGULAR 6 WHITE. ETCHED 5" 2.5% HNO3. EDGE OF PIG. WHITE IRON 3.01 CARBON. ETCHED. 100 DIAMETERS.

qualities, as well as strength, and that such irons are specially marked when made and never shipped to consumers who require those qualities.

The reason why irons with a tendency to spot are deficient in chilling qualities is a point which we have not yet worked out. We have established beyond the possibility of a doubt that it is not dependent solely on the carbon in iron. We have seen two irons of the low No. 4 grade, of which the carbons

were identical within the limits of chemical error (4.06 per cent and 4.07 per cent), and yet the chill on one was about ¼ in. deep, on the other about ¾ in. deep.

It is entirely possible that part of the cause may be the temperature at which the iron is cast. The tendency is, in our opinion, for the chill to be reduced by casting at a higher temperature. It is fairly well established that high hearth temperature (other things being equal) tends to promote high carbon. It may, therefore, be that deficient chill and high carbon are the joint results of the same cause, high hearth temperature, rather than having any relation of cause and effect with one another. It must be borne in mind, however, that as stated in the beginning, there is some other factor, perhaps more than one, affecting the quality of the iron in addition to analysis in the ordinary elements, even including the results herein contained concerning carbon. We have had this fact forced on our attention in so many ways that we feel called on to reiterate it at every opportunity, but I do not wish to go into the details of that subject now.

It is not at first sight obvious why these spotted irons should be confined, roughly, within silicon limits of one-quarter and three-quarters of 1 per cent. The reason is probably two-fold.

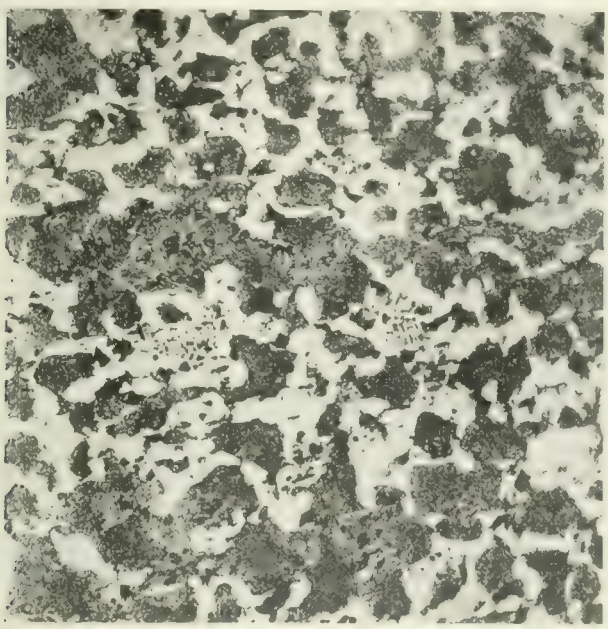

FIG. 22.—WHITE IRON OF 3.30 CARBON. ETCHED. 100 DIAMETERS.

Very little is known about the conditions which control the amount of carbon in pig iron, but two of the facts well understood are that a cold hearth producing white iron gives a low carbon. On the other hand, a hot furnace giving an iron high in silicon also produces a low carbon because of the tendency which carbon and silicon mutually exert toward excluding one another from iron within certain limits. The common illustration of this is "silvery" iron in which the silicon is so high as to keep the amount of carbon absorbed well below the ordinary range, leaving the white of the iron to show through more than the mass of graphite in normal irons will permit. Between these two extremes of low silicon and high silicon the carbon contents of the iron rise to a maximum presumably around ½ per cent in silicon, the hearth not being cold enough when running on these irons to prevent the absorption of carbon on one hand and the silicon not high enough to crowd it out, on the other.

These irons, therefore, under ordinary conditions, are the most likely of any to contain carbon well above the eutectic point, and so to lend themselves to segregation and the consequent formation of the austenite-pearlite eutectic. Moreover, these irons contain enough silicon to throw some of the carbon into the graphitic form as they cool below the eutectic temperature, but they do not contain enough to throw out graphite from the segregated spot against the compression of the solid exterior.

When the silicon is lower than this its effect is insufficient to throw any marked amount of carbon into the form of graphite, below the eutectic freezing point, even though the

FIG. 23.—NEWBERRY HIGH 3. UPPER CORNER OF FIG. 38. DIAMETERS.

iron throws out a little primary graphite while cooling down to that point. Irons higher in silicon, on the other hand, exert so great a graphite-forming tendency as to cause its formation from the solid in the segregated spot, but on account of the pressure the graphite tends to take the nodular form, occupy-

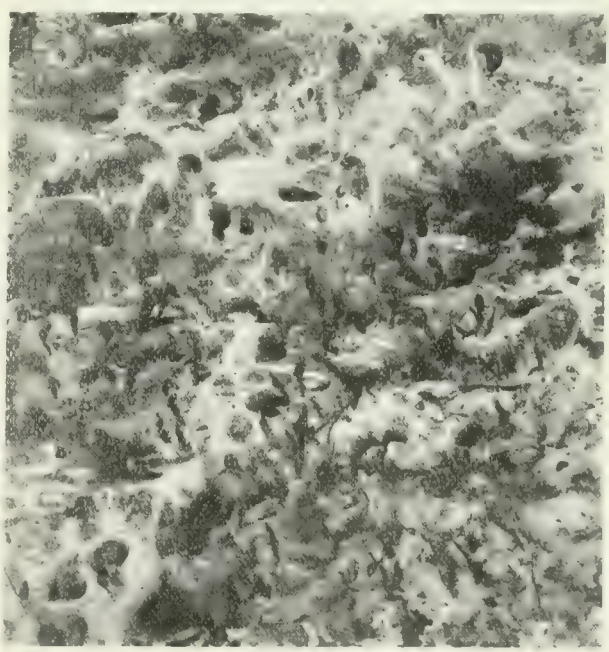

FIG. 24.—NEWBERRY LOW CARBON IRON. ETCHED. 100 DIAMETERS.

ing the least possible room rather than to take its customary flake form. This causes the fine-grained gray structure in the segregated spot.

In regard to these comparatively soft irons with a close spot in the center, it is necessary to exercise great caution in passing judgment. The primitive eutectic plates are so completely broken up that graphite cuts through them as well as parallels

[illegible] [illegible] during the process of breaking down, the [illegible] plates form ribs at right angles to the principal axes of the crystal, and these ribs give an interlacing effect which is entirely wanting in the partially white spotted irons. There is much reason, both practical and theoretical, to believe that some very excellent irons may contain a close spot in the center.

CONCLUSION.

1. Spotted irons are products of carbon segregation.

2. This segregation may take place in irons containing either more or less carbon than the eutectic ratio.

3. The segregation is less marked and less likely to have ill effects the further the carbon is below the eutectic ratio.

4. When the fracture of an iron shows high cleavage at the edge it is almost sure to be up to, or above, the eutectic ratio, and is virtually certain to be a weak iron.

5. Close spots not associated with cleavage may occur in irons of good quality, especially where the silicon is comparatively high.

6. While we have discovered the cause of spotted irons and irons of high cleavage and the reason for their corresponding weakness, it is my firm conviction that there is another condition, element, substance, or what you will, that makes for

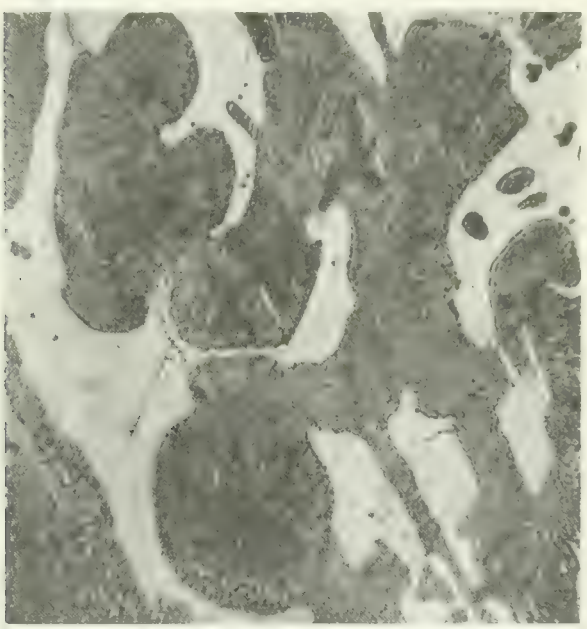

FIG. 25.—NEWBERRY LOW-CARBON IRON. ETCHED. 450 DIAMETERS.

ANALYSIS OF NEWBERRY LOW-CARBON IRON, FIG. 25.

strength and for high chill with a given silicon content in just the same way that high carbon is here shown to make for weakness and low chill with a given silicon content. What this unknown condition may be I do not yet know, though I have some unconfirmed opinions on the subject. But there are many things which make us believe that with this other condition properly fulfilled a relatively high carbon iron may be stronger and better than an iron of much lower carbon, with this condition absent.

In illustration of this it may be well to call attention to cold blast irons which command a price much higher than that of any other kind of pig iron, and which our investigations, nevertheless, have shown to be quite high in total carbon, frequently well over 4 per cent.

We are continuing the [illegible] of the [illegible] at our command to determine what the remaining unknown condition may be, but this paper is designated as a "preliminary paper" to denote our firm conviction that there is far more to be learned on this subject than is contained in this paper. We think we have proven that high carbon by itself makes an iron weak and poor, but low or moderate carbon by itself is not enough. It is my hope that we shall eventually discover what causes good iron to be good, as well as what causes poor iron to be poor, and since we have been able, even with our present relatively slight degree of enlightenment, to improve the quality of our iron and to apply different grades to the service for which they were best adapted, so we have confidence that we shall eventually succeed in producing the grades and qualities we desire, approximately at will.

Ashland, Wis.

Extraction and Purification of Platinum.*

By [illegible]

Since the platinum of commerce is exclusively derived from alluvial deposits, the methods employed for its recovery are essentially similar to those employed in gold placers: indeed, if we except the Uralian districts, it may be said that platinum is generally obtained as a by-product in gold washing.

The Russian platinum-bearing gravels, which are covered with barren material, from a few feet to 50 ft. in depth, are worked partly by open mining, but usually by sinking shallow shafts and drifting along the pay streak. The latter, as a rule, is only a few feet in thickness, and the gravels are said to run from 0.05 to 1 ounce per cubic yard.

The washing plants are mostly of a peculiar, rather primitive construction, though quite recently modern methods and apparatus have been successfully introduced on some of the properties.

(For descriptions and recent improvements in the recovery of platinum, with or without gold, see Mineral Resources, 1905-1906.)

The metal obtained by washing and various concentrating processes, and freed from gold, constitutes the crude platinum, or platinum ore, of commerce. This contains various metals that render the platinum unworkable, and the ore has to undergo a refining process to convert it into the commercial form.

Many attempts to render platinum malleable and ductile were made during the latter part of the eighteenth century, and while a few men, like Achard, the Count von Sickingen, and the skilful metal workers Chabanneau and Jeanetty, of Paris, succeeded in doing it on a small scale, it was not until the early years of the nineteenth century that the platinum industry was really founded, and the creators of this industry were Englishmen.

About the year 1800 Charles Knight devised a process which, while still imperfect, embodied the principal features of the method by which all commercial platinum was obtained for more than 50 years. It consisted in dissolving the crude metal in aqua regia, precipitating the solution of the chloride with sal ammoniac, then packing the dried precipitate into conical molds of fire clay, and strongly heating it in the mold. It is said that the metal was thus obtained as a coherent mass which could be hammered and worked into various forms.

The product, however, still lacked solidity and homogeneity, and it was only by certain important modifications and improvements that it became a commercial success. The improved process is usually credited to the chemist Wollaston, but according to Roscoe the main features were invented by a relative of a member of the firm of Johnson & Matthey.

* A part of a Franklin Institute paper entitled "Platinum, the most precious of metals." In the above we only give the part dealing with the extraction and purification of platinum. The full paper, which also contains notes on platinum minerals, properties and uses of platinum and production and value of platinum, may be found in the November issue of the *Journal of the Franklin Institute*.

However that may be, it is certain that the improved process was first described by Wollaston in the Bakerian lecture for 1828, and Faraday, who was undoubtedly well informed on the subject, said in a lecture on platinum, delivered in 1861, "This substance has been given to us hitherto mainly through the philosophy of Dr. Wollaston."

In the process described by Wollaston the double chloride of platinum and ammonium was very carefully heated to a temperature just high enough to expel the ammonium salt, whereby the cohering of the resulting particles of metal was prevented. The product was then rubbed by hand, sufficiently fine to pass through a lawn sieve. It was then made into a uniform pulp with water, and this was placed into a brass cylinder, where it was powerfully compressed by means of a lever. The hard cake which resulted was heated on a charcoal fire, to expel the water and promote cohesion, and finally heated at the highest temperature attainable in a wind furnace. By forging the white-hot cake under a heavy hammer, it was consolidated into an ingot, which could be beaten into thin sheets and drawn into the finest wire. The refractory natural product had been conquered, and henceforth platinum was one of the useful metals.

That platinum is not infusible was shown in 1758, when Baumé and Macquer succeeded in melting grains of the ore by the aid of a concave mirror; but the melting of considerable quantities of the metal was a feat which was first accomplished in Philadelphia: in 1847 Robert Hare demonstrated that the difficult and tedious process of consolidating platinum sponge could be replaced by the simple operation of fusing the metal in the oxyhydrogen flame. He melted as much as 2 lb. of platinum at a time.

His process was greatly improved by the French chemists Deville and Debray, and it was through them that it became more generally known, and that it was adopted by the platinum refiners.

Deville's furnace consists of two well-fitting pieces of quick lime, hollowed out to form a crucible or hearth. An opening at the side serves as a spout for the molten metal and for carrying off the fumes and products of combustion. The nozzle of the oxyhydrogen blowpipe is introduced through an opening in the center of the cover.

Lime is used because it is infusible at the temperature of the flame, and because it is porous and absorbs the slags formed during the operation. It is also a poor conductor of heat.

I had the privilege of seeing this process in operation at the Heraeus works at Hanau. Although they used illuminating gas instead of hydrogen, it was amazing to see the platinum sponge and scrap melt like butter as fast as it was fed in. You cannot, however, distinguish the metal from the lime, as both glow with the same intensity, and one must also protect the eyes with dark glasses when looking into the furnace. At the Heraeus works I was shown all the principal operations, from the treatment of the ore with aqua regia, to the production of the ingot. Incidentally I also learned how such by-products as iridium, palladium, rhodium, and osmic acid are obtained and handled.

Although several methods have been proposed for the refining of platinum, it appears that the treatment of the ore in the different works is essentially the same; for there is little difference in the manufactured product, whether it come from London, Paris, Hanau, St. Petersburg, or our American refineries.

At the Heraeus works the ore is boiled under pressure with dilute aqua regia, whereby the platinum and some of the associated metals pass in solution in the form of chlorides, while the iridosmium and gangue remain undissolved. The chloride solution is evaporated to dryness and heated at 125 deg. C. The residue is then dissolved in water, acidified with hydrochloric acid and precipitated with sal ammoniac. The resulting double chloride, containing only small amounts of other metals, is finally reduced.

The refining of platinum in the dry way, as proposed by Deville and Debray, does not seem to have proved successful, except in special cases and on a smaller scale.

The preparation of chemically pure platinum, i.e., a product which is entirely free from iridium, rhodium, etc., is extremely difficult and tedious, and need not be discussed here.

Philadelphia, Pa.

Coloration of Fire Clay Products.*

Can the quality and the refractoriness of fire clay products be judged by their coloration? In answering this question it will be advisable to discuss the different factors which may affect the coloring of the burnt clay.

The iron content of the raw material is the great coloring agent of the clay, especially if its amount is high in comparison with the clay base; of further importance are the several impurities of the raw material, especially lime, the composition and temperature of the kiln gases and the density of the burnt ware.

Without regard to carbon deposits caused by a strongly smoky fire, or to superficial soiling produced by the ashes carried along by the kiln draft, the discoloration under circumstances enumerated will be influenced by the iron content of the raw material. The higher the ferruginous admixtures compared with the clay base the darker will be the color.

Since the iron oxide in a finely divided condition and combined with the other components of the clay serves as a flux, raw material showing high iron contents is not considered as a fire clay.

As there are no clays completely free from iron, discoloration produced by the ferruginous parts will always be observed. This same discoloration will occur in the manufacture of Dinas brick by using an iron-containing quartz, which, however, may be of sufficient refractoriness to burn to a useful brick. Although only materials containing very low amounts of iron are used in fire-clay manufacture, the iron percentage may reach as high as 2 per cent, whenever no other fluxing ingredients are present, and in case of a respectively high clay base.

Raw materials with different iron contents and of the same burn will show a difference in coloration without being necessarily different in quality. On the other hand it is possible that a brick of grayish-yellow color and another one of rust-color, both being of the same burn, may show a different refractoriness, and possibly the former may be more refractory. But according to the above remarks the color of the burnt clay cannot be considered to decide the quality of the ware as long as the bricks under comparison are not of the same burn.

The possibility of an examination of this kind is not given to the purchaser, but to the manufacturer this may suggest more thorough tests of the raw materials and products manufactured therefrom.

Concerning the influence of the fire gases, it has been observed that products burnt in an oxidizing atmosphere show every gradation of color from lightly pink to yellow, while products burnt in a reducing atmosphere show in general a more blackish coloration; red coloration may appear after reducing burning by the action of sulphur compounds. Other gradations of color may again occur when the atmosphere will alternately be reducing and oxidizing. The degree of temperature will also account for the gradation of color, so that it seems impossible to recognize the quality of refractory ware merely from the standpoint of its color.

The manufacturer alone may discover himself by a given tint whether one given burn differs from another one, other things remaining the same, i.e., the same composition of raw material and the same firing condition during the entire stage of burn-

*Translated from Tonindustrie Zeitung, No. 1[illegible]

ing. By taking into account the numerous gradations of color which may occur and on the other hand the widely varying iron contents of otherwise good refractory products it seems impossible to a person not acquainted with the manufacturing methods to make a true valuation, so far as color is concerned, solely based on the temperature of the burn.

As to the coloration as influenced by the density a dense body will be of darker color than a more porous body with equal iron contents. But to form an opinion as to the value of the ware in this respect would not be advisable at all, as the coloration may be influenced by one or more of the other numerous factors.

The question whether the quality and refractoriness of fire clay products can be judged by the coloration of the ware, must be answered in the negative. The products of the fire clay industry cannot be judged by their color because there are innumerable factors, which influence the discoloration of the ware. The technical properties are the only ones of value and they have to be determined by special tests and examinations.

Recent Researches on Corrosion of Iron and Steel.

In his report to the Manchester Steam Users' Association Mr. **C. E. Stromeyer,** chief engineer of the association, reviews the present situation in the corrosion problems as follows:

During the past year a considerable amount of important research work has been carried out with regard to the question of corrosion of iron and steel, and though it cannot be said that the mysteries of this complicated subject have been dispelled, much additional information is now available.

Practical experiences indicate that the internal corrosion of boilers is due almost entirely to the presence of air in the boiler water, or rather it is due to the oxygen and the carbonic acid of the air, which are absorbed by water when exposed to the atmosphere. This is a well-established fact, and Profs. Heyn and Bauer, of the Prussian National Physical Laboratory, evidently took it for granted, for they exposed their small experimental strips of wrought iron and steel in open breakers, which were partly filled with waters containing various proportions of corrosive and anti-corrosive salts. If these experiments on various salts are to prove of value to boiler users, the corrosive influence of the air must be reduced, and for this particular purpose it would have been highly desirable if the experiments had been conducted in an artificial atmosphere, with comparatively little oxygen.

However, as it is very desirable that these carefully conducted experiments on corrosion should be turned to advantage as regards boiler corrosion, the corrosive influence of air in feed water must be inquired into in order that its disturbing influence on the results may be discounted. In the experiments the average corrosion amounted to about 70 milligrammes in twenty-two days, which, taking into account the surfaces of the pieces, is equal to about 700 millionths of an inch of thickness in 120 days. Experimental corrosion of one-tenth of this the total, or, say, 70 units, should therefore correspond to very serious corrosion in a boiler, and the experiments, to be of value, should indicate to within 10 per cent of this amount, say, 7 units, whether the addition of a certain salt to any water will increase or decrease the corrosion. Unfortunately, the results do not come up to this expectation, for even among the experiments with distilled water the corrosion varies from 552 to 782 units, and individual results of two pieces of iron placed side by side under identical conditions, which ought to have corroded at identical rates, differed from each other by large amounts, in one case by as much as 158 units, or by twice as much as what may be considered serious boiler corrosion. By averaging results, however, certain indications are obtainable.

The object of the analysis of Profs. Heyn and Bauer's experiments was to ascertain whether any of the salts which they tried would be likely to counteract the corrosive tendency of the oxygen and carbonic acid which are introduced with the feed water. There is no great difficulty with regard to the carbonic acid, for almost any alkalis will neutralize it, but the oxygen can only be removed by letting it oxidize something, and that, no doubt, was the reason why, among other salts, deoxidizers were tried, but no additions were male of alkalies which would neutralize the carbonic acid in the solutions, though it is well known that most photographic developers (these are deoxidizers) require an alkali to make them active. It is, therefore, not surprising that no very pronounced results were obtained. Ferrous sulphate appears even to be an intensifier of corrosion, which may be due to its oxidation resulting in a ferric salt; but in a boiler where the oxygen supply would be limited, ferrous sulphate might be advantageous. A possible reason why weak solutions of sugar had a corrosive effect may have been that in the presence of an excess of air sugar is, perhaps, converted into an organic acid which would corrode iron, whereas with an excess of sugar there would not be enough oxygen in solution to effect this conversion and yet allow enough to remain for corrosive purposes.

The idea of making the oxygen harmless is often carried out in practice. The customary deoxidizers are, however, not salts, but organic substances, notably, tannin compounds. To be most effective they must be associated with an alkali, and it would be correct to introduce them continuously with the feed, then all the oxygen would disappear. The more economic plan, however, would be to maintain a slight excess of the deoxidizer in the boiler, for, as already explained, most of the oxygen escapes out of the water into the steam space, and need not be dealt with, and it is only the small residue which remains in the water that has to be removed. Of course, if the boiler circulation is bad and much stagnant cold water rests in the boiler's bottom, then obviously it would be best to introduce the deoxidizers continuously into the feed. That, too, is the only effective method for checking the internal corrosion of economizer pipes, if these are fed with strongly aerated feed water: but it is probably a costly process, for, after all, it is but a mere trace of the total oxygen in the water which does the harm, yet all the oxygen has to be removed if no harm is to be done.

Another plan is to keep the oxygen out of the feed water, which means that instead of feeding the boilers through the feed pumps of the main engine, which have to be excessively large and which necessarily pump air into the boiler, the feed should be dealt with by slow-running independent feed pumps: and perhaps the recent practice of marine engineers to use high-pressure centrifugal pumps for feed purposes may be equally advantageous. These centrifugal pumps offer the advantage that they require little driving power when the feed valves on the boiler are partially or entirely shut down.

Although the present experiments are somewhat disappointing, they do at any rate point to two very important conclusions which are confirmed by practical experiences. These are that most ammonia salts are powerful corroders of iron, which accounts for the serious corrosion sometimes met with in boilers fed with water that is contaminated with waste liquors from gas works, and, secondly, that when carbonate of soda is added to brackish water (water containing common salt) then severe pitting occurs, although the average corrosion may not be extensive. The protective action of oxidizing acids requires confirmation, if this be possible, by tests on boilers, and the well-known beneficial influences of deoxidizing agents require further scientific investigation.

Of late, certain salts and devices have been invented, which, although they aim chiefly at the reduction of boiler scale, may also counteract corrosive influences. The most sensational of these is the so-called "luminator," which consists of a sheet of corrugated aluminium over which the feed water has to flow under certain conditions of daylight. There seems to be no waste of aluminium, but the lime salts in the water, instead of

being precipitated as hard scale on the heating surfaces, are said to fall to the bottom of the boiler as fine powder.

"Permutit" is a double salt of the following composition: $2SiO_2$, Al_2O_3, Na_2O, $6H_2O$. If water containing lime salts be passed through a bed of this salt, calcium is retained there and sodium takes its place in the water. After a time the operation would cease, due to an excess of lime in the bed; then a stream of salt water is passed through it, and now the process is reversed, the sodium replacing the calcium in the bed of permutit, and chloride of sodium passing away. The bed can then be used again for the purification of feed water. The process is far too costly for the purification of waters containing chiefly carbonate of lime, for in addition to the first cost of the permutit, about 70 lb. of salt are required for the removal of 100 lb. of carbonate of lime.

If the water has permanent hardness (sulphate of lime), the case is more favorable, for every 100 lb. of this impurity would require 74 lb. of soda ash, costing 3s., for their removal in an ordinary softener, whereas with permutit experience shows that about 600 lb. of pure salt, costing about 4s., would suffice. It is, however, very rarely that the water supply has only temporary hardness, and as yet it has not been possible successfully to treat the water, first by the ordinary lime process for temporary hardness, and then with permutit for the permanent hardness. The difficulty seems to be that softened waters deposit lime in the permutit and choke it. Permutit is also not suitable for waters containing appreciable quantities of common salt.

Another very efficient but comparatively costly salt is aluminate of barium. It is preserved from atmospheric influences by being sent out in sealed tins, which must not be opened until required for use. The formula of this salt is BaO, Al_2O_3. The barium combines both with the carbonic acid and the sulphuric acid of the lime salts, forming insoluble precipitates; the lime is also precipitated as well as the alumina, the latter carrying with it most of the organic or greasy substances which may be present in the water. Water treated with this salt is, therefore, almost as pure as distilled water, and ought to be useful for washing purposes. As barium is somewhat poisonous, water purified by its means cannot be used for domestic purposes.

The Slime Filter Patent Decision.

A patent decision of greatest importance in connection with the cyanide process was rendered last month by the United States Circuit Court of Appeals for the Third District in the case of the Moore Filter Company versus the Tonopah-Belmont Development Company. The latter, using the Butters filter, had been sued by the Moore Filter Company for infringement of the Moore patents.

In the lower Circuit Court the decision was in favor of the Butters side. Judge Rellstat held that infringement of the Moore patents by the Butters filter was not shown. Thereupon the Moore Filter Company appealed and the Circuit Court of Appeals (Judges Gray, Buffington and McPherson sitting) has now reversed the decree of the lower court and remitted the cause "with instructions to enter a decree adjudging claims four and five valid and infringed."

Before giving details of the decision it is, therefore, well to quote here claims 4 and 5 of George Moore's U. S. patent 764,486 of July 5, 1904, on which the fight was made and the decision was reached:

Claim 4: "A filtering process comprising submerging a filtering medium in a material to be filtered, drawing the liquid being filtered from said material through said medium until a deposit of solids is formed upon the medium, removing the medium from the material being filtered, further impoverishing the solids by a cleansing operation, and removing the solids from the medium by passing a cleansing current through said medium."

Claim 5: "A filtering process comprising submerging a filtering medium in the material to be filtered, drawing the liquid being filtered from said material through said medium, removing the medium while continuing the drawing action, passing a cleansing fluid through the medium, and then passing a cleansing current through said medium."

Decision of Court of Appeals.

In the decision of the Circuit Court of Appeals, which is written by **Judge Buffington**, a review is first given of the difficulties formerly experienced in cyanide practice with the leaching of "slimes." Various articles written from 1892 to 1902 are quoted to show the seriousness of the slime problem until Moore offered "the first suggestion for the solution of this world-wide problem."

"After a careful study of Moore's patent, we have reached the conclusion that his process is a radical departure from the whole prior art and was an original and pioneer step in metal recovery by filtration. Like all important inventions its merit is its simplicity, and its novelty consists in his utilizing the simple elemental processes of nature. These processes he has, of course, neither discovered nor invented, but he has utilized them in combination in a manner never before used and has thereby secured a new result.

The Gist of the Moore Process.

"Briefly stated, the gist of Moore's instruction to the mining world was to filter an unleachable mass in such a manner as to cake the pasty slime so uniformly and evenly that the resistance of the slimy mass to percolation became uniform and even in every part of the cake. The result of such uniform and even cake-resistance was that when the cake was attacked by the percolating solvent its percolation was correspondingly uniform, and diffusive through the uniformly resistance cake. The solvent having by this uniform and even resisting been itself uniformly and evenly percolated through the mass, it followed that when this percolated solvent was in turn subjected to a propulsive washing current, that such propulsive current, finding no path of least resistance in the uniformly resisting cake or the uniformly percolated solvent, moved forward uniformly and evenly to expel such uniformly distributed percolated solvent. The creation of this uniform and even resistance in the cake is the gist of Moore's process, and such uniformity, as we shall see, is secured by the slime being submerged when subjected to suction."

Extended quotations follow from Moore's description of his process.

"Applying suction to a filter completely submerged is to form an enveloping case or cake of a pasty nature in the filter. As the cake builds up it develops a thickness and compactness which gives the entire cake a capacity of uniform resistance to percolation. For so long as the resistance is not uniform the consequent increased rate of deposit at that point would set up and continue until the rate of flow there became equal to the rate of flow at all other points. The significance of this uniform resistance capacity of the cake, and that it was obtained by filter submergence, is stated in the specification where the patentee, in order to show that after the filtering process is completed an entire enveloping cake of uniform resistance capacity can be simultaneously discharged by compressed air, says that such action is owing to the process having produced an enveloping cake of uniform and even resistance capacity."

"Indeed, of the fact that the result of subjecting a submerged filter to suction is an enveloping cake of uniform and even resistance, there can be no doubt under the proofs in the case. To question it is to dispute the operation of the laws of nature." Statements by two of the defendants' experts, Mr. Julian and Dr. Chandler, are quoted in confirmation.

Prior Art.

"It is contended, however, that the Moore patent is invalid by reason of the disclosures of the prior art. But in our view

[illegible] contention is based on a failure to recognize the true significance of what Moore really did. Practically his problem was to make commercially possible the recovery of a minute amount of valuable metal from a large quantity of mud. Of the fact of the metal being there, there was no doubt, for that fact, and indeed that it was possible to extract it, the tedious and costly method of laboratory filtration showed.

"It suffices to say that no one of the numerous patents cited did such work, used such process, or effected such results, and if none of them led their inventors or users to the use of any process whereby such work could be done, or even led to a suggestion in their descriptive matter of the possibility of the use of any such process as Moore's, it follows they taught Moore no more than others.

"So far as the patent here in question is involved, Moore's disclosure was the process he originated and not the machine with which he illustrated the use of his process in accordance with the statutory requirement that he file a written description 'of the manner and process of using it.' To find, therefore, here and there in prior patents, and disassociated from each other, all the mechanical appliances of the combination apparatus which Moore thus illustratively used is not to prove that Moore's process is not original."

"Viewed from a patent standpoint, the significance of a machine lies not in its form but in the principle on which it works, as will be seen in the requirements of 4888, 'in the case of a machine, he shall explain the principle thereof.' It suffices, therefore, to say that very few of these patents are even for a process, and as none of them operated on the principle or process of Moore, they cannot be held to forestall or minimize the originality of Moore's subsequent disclosure. And in giving these patents their due relation to Moore's disclosure the fact must not be overlooked that the slime problem which Moore solved only came into existence from the use of the cyanide process, which began, as we have seen, about 1887. It will, therefore, be manifest that no patents preceding that date and none subsequent thereto which did not apply to the cyanide process, were calculated to solve the cyanide percolating difficulties, that arose in the use of that process.

Laboratory Versus Industrial Practice.

"So, also, to say that following prior laboratory practice, it was possible to leach and extract the unrecovered ore left in a pasty mass by the cyanide process is not to destroy Moore's patent; for this is to lose sight of the practical working value of Moore's process as a workable, economic treatment, as compared with theoretical possibility of laboratory practice. By repeated dilution the laboratory could, and we will assume did, recover with practical completeness all such unrecovered metal, but this has been done with an expenditure of time, labor and expense out of all proportion to the value of the metal.

"When therefore Moore disclosed a process by which such recovery was made enormously profitable and by which he turned a dump heap which under all known processes, machines, and laboratory methods was worthless, into profitable ore, we are constrained to give little weight to the suggestion that his process was either anticipated, a mere advance incident to the art, or involved no invention."

Non-Diluting and Bodily Displacement of the Solvent Versus Diluting Intermingling.

"So, also, it is said that the step described in his claim, viz.: 'further impovershing the solids by a cleansing operation,' was merely the washing or dilution of the prior art. Considered in its literalism and in isolation, such contention may seem plausible, but considered as a step in Moore's process it takes on new significance and value. Bearing in mind that in the prior steps of the process covered by this claim, the completely submerged filtering medium has formed a cake of uniform resistance at all points and by reason of such uniformity the solvent has percolated and is permeating the cake, it follows that the step which follows is a non-diluting and bodily displacement of the solvent and not a diluting intermingling.

"This displacement in contrast with dilution, not only saves the time and expense of repeated dilution and refilling, but also obviates excessive dilution of the solvent solution and the necessity of rehandling large volumes of diluted solutions in the recovery of the metal. It seems, therefore, that the 'further impoverishing the solids by a cleansing operation' of Moore's process, owing to the prior step whereby a cake of even and uniform resistance is secured by submergence, is not a mere washing or diluting step, but is one wherein there is exerted a uniform pressure or pushing action through the entire cake surface, thereby in effect advancing a wall of water pressure to force ahead of it from the cake the value-bearing solvent liquid, and leave in the cake an equal volume of non-value-bearing water.

"This final result is secured by first having built up a cake of uniform resistance to solvent fluid flow, and secondly by again submerging the filtering medium and its built up cake in the non-value-bearing displacing fluid. By this displacement by pressure difference only Moore pushes ahead instead of washes through the cake contained-metal-carrying fluid. As showing the practically complete metal extraction by the Moore process, we restrict ourselves to the uncontradicted testimony of results at a South Dakota mine, where the original slime contained gold at the rate of $7.90 per ton of dry slime. After filtration alone the cake still contained $2.75 per ton of dry slime. After being then subjected to the displacement step there was left in the cake but four cents of gold per ton of dry slime."

Process Versus Apparatus Patents.

"Being of opinion, therefore, that Moore's process was novel, useful and inventive in character, his patent is valid and we next turn to the question of infringement.

"As claims four and five furnish sufficient basis for deciding that question, so far as the respondent's device is concerned and as some questions, not necessary to be here decided, exist as to claim ten, we restrict ourselves to a consideration of claims four and five.

"In considering the question of the infringement of a process patent, it must be borne in mind that the monopoly secured by the claims is, generally speaking, a monopoly of the process and the test of infringement, is whether such process is utilized by the infringer. As the apparatus shown in a process patent is only to show that the process may be practically applied, it follows that such illustrative apparatus does not limit the process patentee to that type of machine alone. If that were the case a process patent would be of little value.

"So distinctively and separate in the patent law are process and apparatus for utilizing such process that where, after a patent for a process by one inventor a second inventor might patent a novel apparatus for utilizing the process, the situation would arise that the inventor of the process could not employ his process in such machine without license from the machine patentee and the latter could not use the process in his machine without license from the process patentee.

"It will therefore be evident that the test of process infringement is not the similarity of apparatus, but rather whether the apparatus, no matter what its form, utilizes the process. Tested by this standard it is clear to us the respondent's device infringes."

Essentials of a Process Versus Details of Apparatus.

"In form the particular apparatus shown in Moore's patent and the apparatus of respondent vary in the number of tanks, in the differences between changing the fluid which envelops the filtering medium, as in respondent's device by allowing the filtering medium to remain stationary in one tank while the submerging fluid is first drawn off and the second submerging bath is then drawn into the same tank, while in Moore's the

filtering medium is raised from the submerging bath in the first tank and then lowered into the second submerging bath in a second tank.

"But this difference in numbers of tanks and of respective withdrawal and replacing of different baths in no way affects the identity of the process, for it is manifest that Moore could in his patent specification have shown the use of his process, just as well by using respondent's apparatus, had he known of it as his own.

"Both alike use the principle of submergence and intra-leaf suction to create the uniform and even resistance of the cake and both alike use the principle of intra-leaf pressure, Moore using air and the respondent water, to shed the uniformly resisting cake from the filter. For the mere fact of the output being carried off as a dry product in Moore's case to a dump heap and in respondent's in fluid form to a slime pit, does not go to the substance of the process. In the essentials that involve the invention the two are alike.

"Had an apparatus such as respondent's, operated as it is, been in use prior to Moore's there would have been no invention either in the process or in the apparatus shown in Moore's patent. And what, if preceding a patent, would have anticipated it, equally infringes if subsequent. We therefore hold the fourth claim is infringed.

"As we are of opinion and so find from the proofs that there is in respondent's device a 'removing the medium while continuing the drawing action,' the fifth claim is also infringed.

"The decree of the court below is therefore reversed and the cause remitted with instructions to enter a decree adjudging claims four and five valid and infringed and for such action by that court in the way of injunction and accounting as it shall deem fitting."

Hydraulic Classification.*

By G. A. ROBERTSON.

Although numerous methods of classification of pulp for tube milling have been introduced on the Rand within recent years, the spitzlutten in series is still commonly used, and provided it is adjusted to local conditions, good results are obtained. A common error in the lay-out of a spitzlutten lies in the grade of the launder leading from the tailings elevators to the V-shaped or pyramidal boxes being too great, and, together with the impetus given the stream discharging from the elevator, makes difficulty in getting full command over the velocity of the stream through the boxes. This difficulty can, however, be overcome by heightening the box in the last compartment of the series by having a slot above the overflow lip and sliding into this slot the necessary height of wood to reduce the velocity of the stream, this wood traversing the stream. Another method often overlooked is nature's good old rule that the velocity of stream decreases in the inverse proportion as it widens out. Under certain conditions where the first-named method may cause sand to bank in front of the boxes, it may be found advantageous to cut pieces out of the launder on each side of the spitzlutten and widen the stream, commencing a few inches below waterline at the first box. Only fine grades of sand take the extended route, thus allowing better settlement of the coarse sand within its travel zone. The conditions of classification remain fairly constant in this type of classifier. Owing to the small underflows, however, necessary for efficient work, they are liable to choke; but this can be reduced to a minimum by a suitable arrangement of screening in the launders before and after the elevation of pulp.

Adjustment to Variations in Feed

A classifier giving a liquid underflow adjusts itself better to changed conditions than a classfier that gives a low ratio of moisture to solids. For instance, cones, cylinders, V-boxes, pyramids, and other types of classifiers used in series for classifying pulp prior to thickening in a dewaterer, will give, say, from the first box 150 tons of solids per twenty-four hours containing 60 per cent moisture. If the feed is increased, the same size of nozzle may give 200 to 250 tons of solids in the underflow, containing between 40 and 50 per cent moisture Obviously, the volume of solids in the underflow increases at the expense of reduced moisture. On the other hand, take a diaphragm classifier giving an underflow of 300 tons of solids per twenty-four hours containing 27 per cent moisture. If the feed to the classifier be increased, the moisture cannot be reduced more than 1 per cent, and the a coarser overflow is inevitable. Experiments are being conducted with a view to overcoming this difficulty, and a fair measurement of success has already been obtained on one mine, the idea being to automatically increase or decrease the diameter of the underflow nozzle in accordance with the load. Hanging up stamps at week-ends is responsible for the settled sand in such classifiers breaking away, unless the reduced load has been noticed and the underflow adjusted accordingly. On another mine a ball suspended centrally in the classifier has proved its merits by steadying the underflow and permits the depth of settled sand being kept at a low level in the classifier consistent with a low ratio of moisture in the underflow.

Where a diaphragm classifier is used as a separator of sand from slime, an automatically regulating underflow ought to be welcomed. There may be objections to the same idea for tube-mill classifiers, but I think that it is better to underfeed a tube mill and allow for its taking an increased load rather than have constant conditions in the classifier underflow and coarse sand overflowing the classifier without the tube mill having been tried on the increased load.

Instead of diluting a thick underflow after its leaving the classifier, a good plan is to have a stream of water just below the diaphragm. The necessary moisture for tube milling can thus be added inside the classifier from a 1-in. pipe attached to a rubber hose and water service. The required moisture for the underflow is then regulated from a valve, and the pipe can be lowered and raised to the most suitable height. The nozzle can be reduced to 1¼ in. diameter, and the underflow is discharged at a high velocity. On one mine this method has proved very satisfactory, more so than adding water to the discharged pulp.

Classification for Tube Milling

Changes in the feed and moisture entering large conical classifiers under working conditions sometimes cause sand to bank up in these classifiers, thereby forming a "dead end" and decreasing the capacity of the cones available for classification. This is particularly noticeable where a tube-mill plant is working at fullest capacity and giving a medium-grade overflow from the classifiers of about 15 per cent plus 60 grade pulp, or the equivalent to that which would pass a 1200-mesh screen in single-stage crushing. On the other hand, however, where a fine overflow is desired of about 5 per cent plus 60 grade, and under, the tube-mill classifier is encroaching upon the province of a separator of sand from slime, for which it is an ideal machine, and no appreciable "dead end" is formed. This depends to a great extent on the number of tube mills to stamps and the ratio of solids to moisture leaving the stamps. Of course, sand held in suspension in classifiers can be prevented by increasing the size of the underflow, but as far as tube milling is concerned, classification of pulp is the sorting into a limited tonnage of that portion of pulp desired for recrushing, and in that respect I have sometimes been puzzled to see where classification came in at all when between 400 and 450 tons of solids constituted the average feed per tube mill. These large tonnages are claimed to give the best results on some plants, while on others a tube-mill feed not exceeding 300 tons gives the best results. Where amalgamation is not practised in the stamp mill, nor in the classifier overflow, the larger feed to the

*From the South African Mining Journal, September, 1912.

tube mills the greater the percentage of gold recovered by amalgamation in the tube-mill circuit.

In order to overcome the difficulty of fine sand resettling and silting up classifiers, the classifier designed by Mr. H. Stadler is undoubtedly an improvement on the ordinary cone. At the bottom of the central feed pipe to this classifier the area of the cone is greatest, so as to allow settlement of the solids from the level of release of the pulp into the classifier. From that point, having sorted out that portion of solids required in the underflow by means of a truncated cone, the velocity of the upward stream is gradually increased, thereby preventing "dead ends," which otherwise are formed in the ordinary cone by the decreasing velocity of the upward stream.

Even Distribution of Feed.

A cone centrally fed and having a horizontal baffle on the bottom of the feed pipe does not give an even distribution of feed into the cone. In order to see this, however, the cone has to be working at fullest capacity. Further, air is carried down the feed pipe into the cone, and it rises to the surface in the form of air bubbles, bringing coarse sand with it, which, if near the overflow lip and not confronted with a baffle, causes coarse sand to pass in into the overflow. Some mines employ a sleeve around the feed pipe to catch the air bubbles. On the ground that if no air was carried into the liquid none could rise to the surface, the writer placed an iron plate partly over an 8-in. feed pipe to a diaphragm classifier. The conditions allowed a 20-in. "head" being obtained over the feed pipe. No air was then carried down, and the overflow level of the classifier was free from air or other disturbances. The feed to the classifier was increased, still keeping the 20-in. head, and it was seen that the distribution of feed to the cone was not even, thereby causing at intervals upward currents of coarse sand which were free from air. In order to get better distribution into the cone and still prevent air from getting into the classifier, a better method was to maintain the "head" from the bottom of the feed pipe. Mr. C. W. Dowsett then applied a self-regulating device which consisted of a circular plate, 7 in. in diameter, with three lugs projecting upwards. These lugs acted as guides when the plate rested on the horizontal baffle at the bottom of the feed pipe. This plate was then suspended from a bolt which went to the top of the launder, and was attached to a horizontal piece of wood 2 in. wide, ½ in. thick and 6 ft. long. One end of the wood was made fast to the top of the launder, while the other end suspended the bolt carrying the lugged plate. With a normal feed, the lugged plate was about 1 in. above the horizontal baffle, and a head was obtained from this point up to 20 in. above the inlet of the pipe. As the feed increased, the lugged plate was forced downwards, thereby increasing the release area of the feed pipe and allowing a greater feed to pass into the classifier. Similarly, as the feed decreased, the lugged plate rose and the "head" remained constant within certain limits. Owing, however, to the limited area of the cone at the bottom of the feed pipe and the increased velocity of the feed caused by maintaining the "head" already referred to, together with a slight unevenness in the distribution of pulp into the cone, the tendency is for settled sand to be distributed, thereby causing upward currents of coarse sand. The distributing shoe used in the Stadler classifier would appear to overcome this difficulty, and even though the air may be carried down the pipe, it is in a fine state of division in the classifier and classification is not retarded by its presence.

A change from one classification system to another does not mean that finer overflows are to be obtained by the new classifier. If, however, the assay value of the overflow has been reduced by the new system of classification, then it can be safely said that improved classification has been obtained.

Classification in Grinding Pans.

The swirl of pulp from centrifugal motion of the shoes in a grinding pan causes the surface of the liquid to keep a concave shape, and the particles of sand, on being crushed, rise in the liquid, the tendency being for these fine particles to be forced to the periphery of the pan. In order to obtain advantage of this classification, the discharge of such pans should be from the perimeter. This is easily understood, but not always realized, because the Holman grinding pan, which was tested on the Rand five years ago, did not prove a success, a contributory factor to its failure being that the discharge of the pan was upon a wrong principle. This pan had a peripheral inflow and central discharge through a perforated reversed cone. The design of the pan necessitated a peripheral feed, but that was no reason for a central discharge, which was fundamentally wrong. The discharge could advantageously have been placed on the perimeter opposite the inflow.

Separation of Stamp-Mill Pulp and Tube-Mill Pulp.

Two elevations of pulp are often required in new milling plants. There is no occasion, however, for the two elevations of pulp for purely classification purposes, because the stamp-mill pulp and tube-mill pulp can be kept separate with only one elevation of pulp. The best classification of pulp is obtained where these products are kept separate, but this is only marked where medium grade overflows of about 15 per cent plus 60-grade pulp is desired.

The tendency is for new milling plants to produce about 60 per cent slime, and in that case classification of pulp is almost a separation of sand from slime, and it is doubtful if any improvement in classification by keeping the stamp-mill pulp and tube-mill pulp separate by double pumping would be offset by the cost of the second elevation of pulp.

Mixing nine-mesh products and tube-mill outflows in the same classifier is wrong in principle, because different sizes of particles have different velocities, as pointed out by Mr. R. Boss,[1] and the tendency in hydraulic classification with mixed feeds is for the light material to follow in the path of the coarser particles.

Put to a practical test Mr. Boss's observations, but instead of dropping pebbles into the same glass vessel, have two vessels. Procure fine particles of quartz and particles of pyrites of equal value, and note their difference in the time for settlement in separate vessels. Also test mixed feeds in one vessel.

The only conclusion the careful observer can arrive at is that, in order to get the best results in classification, each grade should be sized and fed to a separate classifier. When this proposition becomes economical, it will be possible to obtain from separate overflows products which, after dewatering, contain neither pyrite nor gold. It is, of course, possible with present methods of classification to obtain a plus 60 grade product which contains but little pyrite or gold, as recently pointed out by Mr. H. Stadler in a rather spirited article, "The New Metallurgy," which appeared in the *Rand Daily Mail*. Only a very limited percentage of the total ore crushed could be obtained of this class. It is apparent, however, that while development takes place in the cheapening of the means of ore crushing whereby the sand is separated to be then slimed, there is still a wide field for research in hydraulic classification. No metallurgist will then want to cyanide barren sand.

Application of the Moore Filter to Rapid Filtration and Purification of Sewage.

On November 20 we had an opportunity of witnessing a very successful exhibition of a new sewage purification process at the laboratory of the Moore Filter Company in New York City, at which representatives of the water departments of various Eastern cities were present.

It is essentially an application of the well-known Moore filter to rapid sewage filtration. The chemical features of the process are the invention of Mr. James M. Neil. We expect to give a full description of the process in our January issue.

[1] "Segregation of Solids in Liquid," Mining and Scientific Press, September 9th, 1911.

The Role of Alumina in Copper-Slag Formation.

The mooted question of the part played by alumina in the formation of slag in copper smelting was referred to in our issue for October, 1912, page 693, where we gave an abstract of an address by Mr. H. C. Bellinger, president of the Australasian Institute of Mining Engineers. Mr. Bellinger related his experiences in several countries, among others Canada. We are able to present the following additional notes on Canadian experience, relating to the same ores with which Mr. Bellinger had to deal about a decade ago. The discussion is contributed by **Mr. J. Buchanan,** metallurgist for the Consolidated Mining & Smelting Company, of Canada, Ltd., at Trail, B. C., and **Mr. F. E. Lee.**

"The subject of the behavior of alumina in copper slags has of late been given much attention at the smelting works of the Consolidated Mining and Smelting Company, of Canada, Ltd., at Trail, British Columbia, and while we have not yet arrived at any definite conclusion in regard to its behavior in our slags, we have worked out a formula which gives very satisfactory results in our case.

"Taking an average monthly slag with the following composition:

FeO	SiO_2	CaO	MgO	Al_2O_3
16.1	44.0	10.2	2.5	17.4

(1) Figuring alumina as acid oxygen, ratio is 1:3.14.

(2) Figuring alumina as basic oxygen, ratio is 1:1.28.

(3) Figuring alumina as neutral oxygen, ratio is 1:2.33

"It will be seen that in case (1) we have an impossible slag, in case (2) a slag which appears too basic, judging from the appearance of our slag here, and case (3) is slightly on the acid side.

"In our calculation we assume that the CaO present combines with the requisite amount of Al_2O_3 to form the silicate of lime and alumina with the composition Al_2O_3, 3 CaO, 6 SiO_2, this alumina acting, of course, as a base and any excess over the amount required for this formula will act as an acid.

"Figuring the above slag on this basis, we have:

	Per cent.	Units O.
SiO	44.0	23.47
Al_2O_3	17.4	8.17
CaO	10.2	5.40
FeO	16.1	3.57
MgO	2.5	1.00
	90.2	41.70

"Leaving one oxygen equivalent of Al_2O_3 to one of CaO on the basic side and moving the balance of the Al_2O_3 oxygen to the acid side we have:

	Acid.		Base.
SiO_2	23.47	CaO	5.40
Al_2O_3	2.68	MgO	5.40
		FeO	3.57
	26.15	MgO	1.00
			15.55

which gives ratio base to acid 1:1.68, a good economic slag.

"Figuring all the slags mentioned in Mr. Bellinger's article on this basis, the result is a good practical slag in each instance and similar results have been obtained from calculations on many other slags which have come under our notice.

"Our experience here is that the amount of alumina acting as a base is determined by the amount of lime present in the slag, and the addition or subtraction of lime to or from the charge beyond certain narrow limits proves this to be the case. It is quite probable that some other bases may act in the same capacity as lime."

In this connection two A. I. M. E. papers by Mr. Johnson and Prof. Fulton, noticed elsewhere in this issue, are interesting.

Recent Copper Milling Practice at Lake Superior.

Editorial Correspondence.

The "copper country" of Michigan is confined to a small area of land known as the Keweenaw peninsula, jutting out into the center of Lake Superior from its south shore. The concentrating mills of the district are grouped at various points of vantage on the lake shore, where the large volume of water required by local practice can be conveniently obtained, and where suitable dumping places are available for large quantities of tailings. The map shown in Fig. 1 gives an outline of Keweenaw peninsula, and the numeral references show the situation of the principal groups of mills and smelters.

In general, the practice of concentrating the metallic copper ores of Michigan is fairly well known. Here the steam stamp has been developed to its highest degree of perfection, being found indispensable in crushing the tough, unyielding rock in which the copper has been deposited. The metal is recovered in a variety of forms and sizes, from the huge masses weighing many tons each, to the smaller masses of several pounds weight which are sorted out ahead of the stamps, ending with the coarse metal and metallic slime produced by the jigs and tables. It can readily be imagined, therefore, that many features of the milling practice have been developed to meet the distinctive local conditions which prevail in no other copper producing district in the world.

Modern Steam Stamps.

In Fig. 2 is shown the Nordberg type of steam stamp which is now being used in the newer installations. These stamps are of the steeple-compound type, with cylinders mounted on round column framing of very rigid construction, and standard mortar with solid anvil blocks below.

The low-pressure cylinder is placed above the high-pressure, and connected thereto by means of a distance-piece of cast iron, giving access to the stuffing-box. The high-pressure cylinder is also mounted on a distance-piece, for the same purpose.

The cylinder heads are so constructed that they will break out in case they are struck by the pistons, thus saving the balance of the machine from destruction in case of such accident.

The low-pressure cylinder is provided with Corliss valves at top end only, for the downward stroke. The high-pressure cylinder has valves at both ends, the lower valves controlling steam admission and exhaust below the high-pressure piston for the purpose of raising the stamp shaft, etc.

The valve gear is of Nordberg patent type with double disc differential motion. There are six eccentrics, one for each valve, the eccentrics driving the lower high-pressure valves and the low-pressure valves being mounted on the pulley shaft, while those driving the upper high-pressure valves are mounted on the secondary shaft. Graduating dials are provided for each eccentric, indicating the position of their central lines relatively to each other. By this arrangement it is expected to get a higher economy in steam than with the old arrangement now used, this economy resulting mostly from a free exhaust at the bottom, whereby the vacuum carried by the condensers can be more fully realized on the stamp piston than with the arrangement where only one valve is used to control the distribution of steam at the lower end of the cylinder. It is also plain that by this arrangement a more delicate adjustment of the steam distribution to both ends of the stamp can be obtained than by a two-valve arrangement.

The bearings on which the secondary shaft is mounted are fitted to a slide wherein they can be adjusted in such a manner that the ratio between the fast and slow motion can be varied between wide limits.

The flywheel on valve-gear shaft is turned on rim and edges, and adapted for belt drive. No loose pulley is used in connection with this arrangement, but it is expected that a tightener will be employed to stop and start the valve motion. Arrangements are made whereby the admission to the top and bottom

Stamps can be made endwise controlled. A releasing receiver is provided between high-pressure and low-pressure cylinders.

Pistons are made of cast steel with cast-iron packing ring. Piston rods are of forged steel with flange at lower end connecting to stamp bonnet. The bonnet, or connection between piston rod and stamp, is fitted with a cushioning disc of rubber. Stamp shaft guides are formed in the framing and are fitted with phosphor-bronze boxes, arranged so as to be easily and quickly removed.

The Importance of Regrinding.

The copper ores of Michigan are not high grade, averaging perhaps 1 per cent copper. The following table gives the copper content of the ore from several of the prominent mines of the district.

	Copper Lb. per ton.
Calumet & Hecla	[illegible]
Ahmeek	24.7
Allouez	16.5
Centennial	17.3
Isle Royale	16.4
Tamarack	[illegible]

Quincy	[illegible]
Wolverine	23.4

In view of these conditions it becomes necessary to carry copper extraction to the farthest point consistent with profit, and it is not surprising that in the last few years a great deal of attention has been given to the matter of finer grinding and additional concentration. The newer mills are carrying out this idea as part of the general scheme, while the older plants are being equipped with regrinding departments for current and accumulated sand tailings.

The Chilean mill was first used as a regrinding machine. The most notable installation was made at the Calumet & Hecla mills on Torch Lake in 1909, at a cost of about $400,000. The equipment consisted of forty-eight Chilean mills arranged in two rows and driven by eight 250-hp motors. Two hundred Wilfley tables concentrated the reground pulp. This plant proved its ability to re-treat current sand tailing at a profit. In [illegible] the recovery was reported to be [illegible] lb. copper per ton of tailings, at a cost of 5 cents per pound of metal recovered. The sands treated contained up to 12 lb. copper per ton, being the tailings from the stamp units treating high grade ore in the Calumet mill.

Following the successful treatment of current tailings, the accumulations of old tailings received attention, and their retreatment was considered. In the early days of Calumet & Hecla, the grade of the ore was three or four times as high as at present, and the tailings likewise were richer. Possibly some of them were equal in grade to the original ore now treated. These old accumulations are the most extensive in the world, aggregating probably 40,000,000 tons of material containing from 10 to 25 lb. copper per ton, the older being probably the richer.

Before building a new plant for the treatment of these tailings, the merits of different regrinding machines were tested over a long period of time. Standard tube mills and Hardinge conical mills were placed in competition with the Chilean mills, with the result that the Hardinge mill was demonstrated to be best adapted to the work. Tests on the old tailings showed that a recovery of about 5 lb. copper per ton could be made profitably; and a new regrinding plant of Hardinge mills is now being built, to have a capacity of 3000 tons per day. Further reference to the use of regrinding will be made in the following description of one of the newest mills.

The Ahmeek Mill, Hubbell, Mich.

The Ahmeek mill is situated on the west shore of Torch Lake, near the town of Hubbell and south of Lake Linden, where the Calumet & Hecla mills are built. It is one of the newest mills of the district and reflects modern methods of construction, being built wholly of structural steel and concrete. It is particularly interesting because it gives an opportunity to compare former and later practice. Work was started in 1910 with two stamps, and later the capacity was increased by the addition of two more stamps in 1911. Two systems of concentration were thus installed with two stamps at the head of each. The essential differences between these two systems will be pointed out later. According to present plans four more stamps will be added in 1913, with concentrating units modeled on the later practice, and the two older units will be changed to conform thereto.

Capacity of Bins and Stamps.

The mill building is connected with the Mineral Range railroad by a steel trestle which reaches a height of 108 ft. at the mill. Ore is brought into the mill over this trestle and dumped into four steel bins, one for each stamp. The bins are quatrefoil in horizontal section, their largest diameter being 30 ft. and their height 42 ft. Each has a capacity of 1000 tons of ore. From the bins the ore flows by gravity to the stamps, which are of the pattern already described. Mass copper is sorted out by hand as the ore passes through the feed chute. The stamps make 106 strokes per minute and are provided with a signal which warns the operator when the bed of ore on the die is becoming too thin for safety. The high-pressure cylinder receives steam at 140 lb., and the low-pressure cylinder at 35 lb.

The capacity of these stamps is tremendous to one who is familiar only with the gravity stamp which is such a common machine in western gold mining regions. Those at the Ahmeek crush 625 tons of ore per day each, with far less noise and vibration than would accompany the operation of a 50-stamp gold-mill. The mortar boxes are fitted with two screens, steel plates punched with 5/8-in. round holes, placed in front and back. In the ordinary course of operations these plates last about three weeks. The stamp shoes weigh about 700 lb. when new, and have a useful life of about 13 days. At the end of that time they are worn to a weight of from 300 to 325 lb. and are removed.

The mortar boxes are fitted also with a device for removing mass copper of fist-size and smaller, which may have escaped the eye of the feeder, or may have been liberated from the

rock by the stamp. This consists of a pipe connection with the mortar box, through which water is forced into the mortar under such pressure that the copper can pass down the pipe against the stream, while the lighter rock is restrained and kept in the mortar for further crushing. These hydraulic mortar-cleaning devices are of great assistance in maintaining the capacity of the stamp by removing metal which it would be useless to try to crush, and by rendering it unnecessary to open the mortar for periodical cleaning by hand.

Earlier Concentrating Practice.

The 5/8-in. mortar discharge flows from the stamp to four hydraulic cleaners similar in principle to launder classifiers and serving the same purpose as the hydraulic mortar cleaner. These remove coarse metal, 5/8 in. and smaller, as concentrate

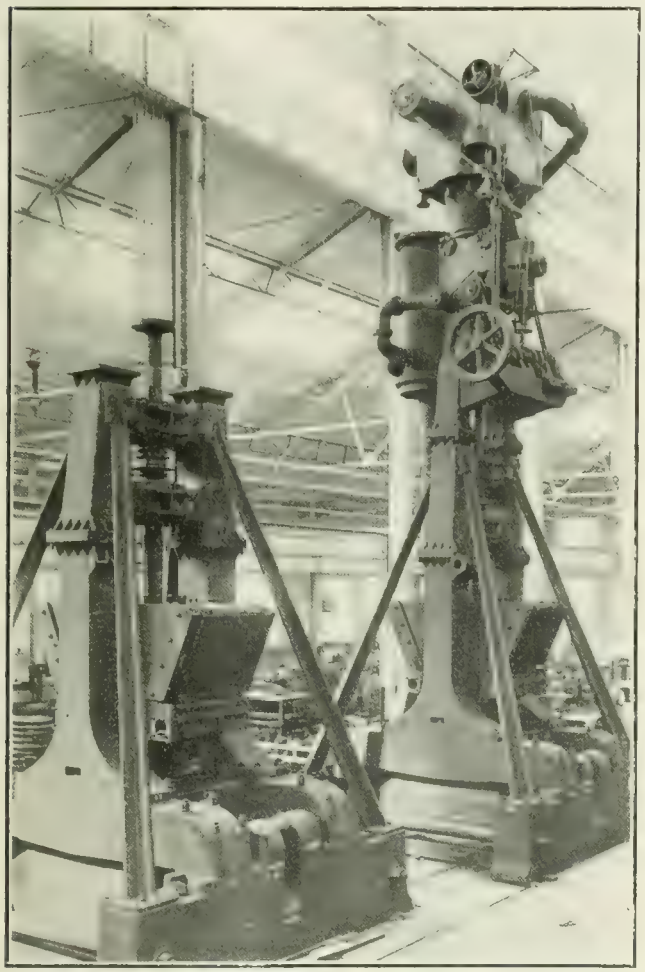

FIG. 2.—NORDBERG STEEPLE—COMPOUND STEAM ORE STAMPS IN COURSE OF ERECTION.

for shipment. The balance of the pulp passes on to four conical trommel screens of 3/16-in. mesh. The oversize of these screens is returned by elevator to the stamp for further crushing. The undersize is again subjected to hydraulic treatment after which the pulp is distributed to jigs.

This hydraulic treatment is one feature which has been abandoned in the newer half of the mill where, according to later practice, the same work is better done by Woodbury bull jigs. An objection to the hydraulic system is found in the fact that, owing to the high water pressure required to keep rock from mingling with the removed copper, smaller pieces of metal remain in the pulp and pass on to the jigs, burdening them unnecessarily and necessitating undue skimming. Further, the product of the hydraulic discharge is not as clean copper as that produced at the corresponding point by the Woodbury bull jig. Again, the oversize of the trommel which is returned to the stamp is not as free from copper as is the bull jig tailing, and as a consequence some copper is kept circulating through the stamp, with probable loss of metallic slime due to abrasion and comminution.

Roughing and Finishing Jigs.

Taking up again that portion of the pulp (minus 3/16-in. mesh), which flows to the roughing jigs, we find it first hydraulically classified into four spigot products and a slime overflow. The jigs are arranged in sets of four two-compartment machines, each receiving one of the spigot products from the classifier. There are eight sets of these jigs, or thirty-two in all. They run at about 160 r.p.m., the stroke varying from 3/4 in. to 1 in. on the different feeds. The screens vary from 8 to 14-mesh. The plunger mechanism is arranged to give a quick pulsion stroke with slower return.

The roughing jigs are skimmed every two hours to remove the accumulation of coarse metal which escapes removal in the hydraulic separators. The hutch material is not a clean concentrate and is re-treated on a set of Hodge finishing jigs. As there is no regrinding apparatus on this side of the mill, the tailings from the roughing jigs are run to waste.

The finishing jigs run at a higher speed than the roughers and have shorter strokes. Their tailings are run to waste. The concentrates from the first compartments are clean enough for shipment, but those from the second compartments are re-treated, half going to another jig and half to Wilfley table. The tailing from this last jig also is treated on the Wilfley table, which makes concentrate and tailing, the latter being wasted.

Treatment of Slime.

Several slime pulps from different parts of the system are collected, thickened and treated on tables. The overflow from the classifiers at the roughing jigs is thickened and classified into two products. The fine is sent to six Evans 3-deck revolving round tables, having smooth pine decks revolving about once per minute. The concentrates from these round tables are re-treated on two Wilfley tables which make concentrates, middlings and tailings. The middlings are combined and treated on another Wilfley, and the tailings are wasted. The coarse slime from the classifier is treated on four Wilfley tables, making concentrates, middlings and tailings. The middlings are retreated on a fifth table and the tailings are wasted.

Later Concentrating Practice.

The principal points of difference between the later and earlier methods are (1) the use of Woodbury bull jigs instead of hydraulic separators, (2) the regrinding of jig and tables middlings, (3) the abandonment of the Evans round tables, and (4) the use of Woodbury slime classifying jigs instead of hydraulic classifiers and Hodge roughing jigs.[1]

The west half of the mill, with two stamps, typifies recent practice. The 5/8-in. stamp product flows directly to four conical trommel screens of 3/16-in. mesh, similar to those on the other side of the mill. The oversize from each pair of trommels is combined and treated on a Woodbury bull jig from which coarse copper is withdrawn from a central gate and dam on the screen. The tailing is returned to the stamp by an elevator, and the hutch product is sent to finishing jigs.

The superiority of this method of recovering coarse copper has already been touched on in speaking of the deficiencies of the hydraulic method used in the other half of the mill. The jig concentrate is cleaner metal than is obtained in the hydraulic discharge, and the jig tailing which is returned to the stamp carries less free metal than does the corresponding material in the older system.

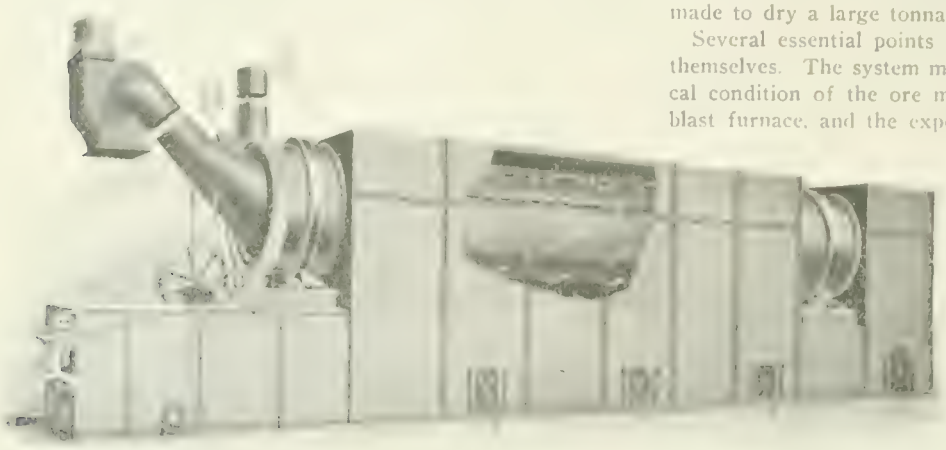
Slime Classifying Jigs.

The 3/16-in. undersize from the trommels flows to four Woodbury slime classifying jigs, comprising a slime-classifying compartment and three jigging compartments. The classifier compartment has 10-mesh screen and the jig compartments

[1] An article on the Woodbury system of classification and jigging appeared in this journal, November 1912, page 759.

much. The classifier effectually removes slime from the pulp as can be seen by inspection of the jigs and tables which follow it, these being freer from slime than the corresponding machines on the other side of the mill. The other products of the classifier are copper concentrate and sand. The copper is removed continuously by gate-and-dam discharge, and the sand flows to the jigs.

The first jig compartment produces copper and the second and



third compartments deliver a middling through an adjustable opening in the lower side of the compartment which permits only the bottom portion of the bed to pass out. These middlings are combined and reground in a belt-driven Hardinge conical mill containing 7500 lb. pebbles and consuming about 100 lb. pebbles per day. The tailings from the rougher jigs are wasted, but the hutch material is combined with a similar product from the bull jig and classified for treatment in Hodge finishing jigs which make screen and hutch concentrates, and tailings.

Table Concentration of Sand and Slime.

The tailings from the finishing jigs are treated on four Wilfley tables. The middlings from the latter are combined on a fifth table, the tailing and middling of which are reground in a second Hardinge mill. The products of both Hardinge mills are treated on six Wilfley tables. These make concentrates of shipping grade, tailings which are wasted, and middlings which also are treated on that table which sends its middling and tailing to the second Hardinge mill.

The slime from the Woodbury classifier is treated on twelve Wilfley tables the middlings from which are treated on one middling table which makes concentrate and tailing.

All tailings except those from the lowest tables in the mill run to Torch Lake by gravity, being sampled automatically in a small building outside the mill. The cement floors of the mill all drain to a common sump from which slime is periodically removed and run over a concentrating table.

On the whole, the newer practice is more satisfactory than the old, for reasons already mentioned; and it is probable also that the recovery is slightly greater by reason of the more prompt recovery of coarse metal and the re-treatment of reground middlings and tailings.

High Speed Iridium Steel.

The latest achievement in high-speed tool steels is recorded by the Becker Steel Works, of Crefeld-Willich, Germany, in a full-page advertisement in the *Kölnische Zeitung*.

It refers to the use of iridium for high-speed steel and high claims are made for it. The use of iridium is certainly novel.

Drying Iron Ore on the Mesabe Range.

Some of the iron ores mined on the Mesabe range in Minnesota contain so much moisture that its elimination prior to shipment is a matter of economic importance. Some minor efforts have been made heretofore along this line, but not until the M. A. Hanna Company erected a large drying plant for the Brunt mine, at Mountain Iron, Minn., was any attempt made to dry a large tonnage of iron ore.

Several essential points in such a plant immediately suggest themselves. The system must have a large capacity; the physical condition of the ore must not be impaired for use in the blast furnace, and the expense of the drying operation should not exceed, at most, the cost of freight on the moisture in the wet ore.

When completed, the drying plant of the M. A. Hanna Company will have a capacity of 3000 tons per day. The plant provides for five Atlas dryers, each of 40 tons capacity per hour; but as the entire plant will not be continuously in operation, it is estimated that a capacity of only 3000 tons per day will be maintained steadily.

The wet ore contains from 16 to 18 per cent moisture, and the dried product about 3 per cent. The ore is first thrown onto grizzly, 4½-in. spaces, the oversize from which is crushed in a gyratory crusher and returned to the grizzly. This system secures a thorough mixture of the lump ore with the fine, which is wetter, and avoids sending large compact masses of wet fine ore to the dryers. From the bin beneath the grizzly the ore is carried by belt conveyors to the dryers, which are of the revolving cylinder type, made by the Atlas Dryer Company, Cleveland, Ohio.

The drying cylinder is designed so that a large volume of dry hot air may be drawn through openings in the cylindrical wall and come in contact with the wet ore. The cylinder may be likened to a large trommel screen, with the openings so guarded on the inside that no ore can fall out during its passage from the feed inlet to its point of discharge at the other end of the cylinder.

In Fig. 1 is shown the cylinder in place, surrounded by a steel casing like a boiler setting, with adjacent firebox to provide heat, and exhaust fan to induce a draft of heated air

FIG. 2.—DRYING CYLINDER SHOWING AIR INLETS.

through the cylinder. Openings *G* in the casing provide for the admission of air, which being heated by the fire, passes into the cylinder in contact with the ore. At the Hanna plant the fan draws 28,000 cu. ft. of air per minute through the cylinder. The temperature of the air entering the casing is about 60 deg. Fahr., while that of the air passing out through the vapor bonnet is approximately the boiling point of water. Eight pounds of water is evaporated per pound of fuel burned.

The relation of the firebox to the casing and cylinder is such that the hottest air is drawn into the cylinder at the feed end where the ore is wettest. The temperature of the air entering the cylinder diminishes toward the discharge end, as does the moisture content of the ore. Likewise the suction of the fan is greatest at the point where the ore is wettest and the air hottest, diminishing toward the discharge end of the cylinder

where the moisture in the ore and the temperature of the air are greatly reduced. In this way the volume and temperature of the air are proportioned to the moisture to be removed.

The drying cylinder is shown in Fig. 2, the horizontal rows of air-inlets being shown on its central portion. Fig. 3 gives an enlarged view of one of the air inlet castings which are

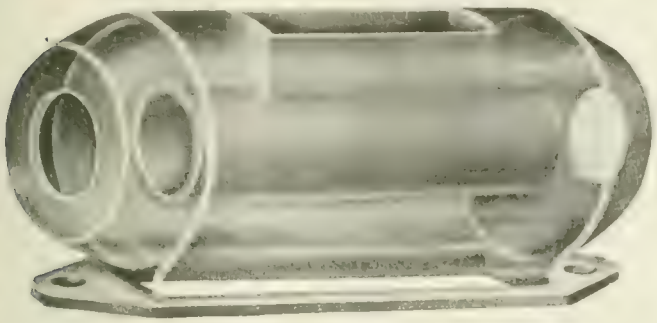


FIG. 3.—AIR-INLET CASTING.

attached to the cylinder. By reference to Fig. 4 the reader will observe the position of the castings on a section of the cylinder, also the means for preventing the ore from falling through the air-inlets. The castings are placed in recesses in the cylinder wall, and within the cylinder are metallic blades guarding

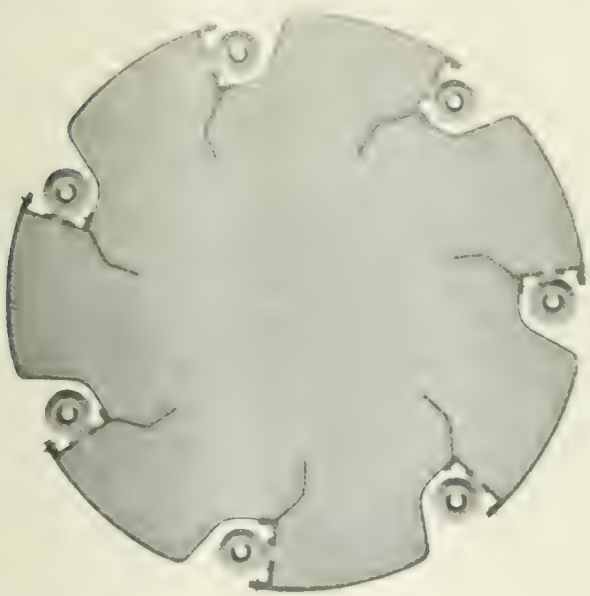

FIG. 4.—CROSS SECTION OF DRYING CYLINDER.

the air openings. These blades serve also to raise the ore and allow it to fall through the heated air during its passage through the cylinder.

The drying of iron ore in commercial tonnages is still a new industry on the Missabe range, but with the introduction of successful drying apparatus it may become more extensive.

Natural Gas.

According to the U. S. Geological Survey, the quantity of natural gas produced in the United States was practically the same as in 1910, while the value increased from $70,756,158 to $74,127,534, a gain in value of 4.76 per cent. The conditions of production were particularly interesting in Ohio, which as a consumer of gas in 1911 takes second place, having consumed 12,123,029,000 cubic feet, valued at $22,792,270. The total quantity of gas produced in this State was 49,449,749,000 cubic feet valued at $9,367,347, compared with 48,232,406,000 cubic feet, valued at $8,626,954, in 1910. The difference between the gas produced and that consumed in Ohio shows the quantity piped into the State from West Virginia and Pennsylvania.

Notes on Chemistry and Metallurgy in Great Britain.

(From our London Correspondent.)

The Iron and Steel Institute.

The autumn meeting of the Iron and Steel Institute was held at Leeds in the Hall of the Philosophical and Literary Society and extended from Sept. 30 to Oct. 4.

Two papers by Sir Robert Hadfield on "A Method of Producing Sound Ingots" and "On a New Method of Revealing Segregation in Steel Ingots," and a paper by Dr. Hans Goldschmidt (of Essen) on "A New Method for the Improvement of the Soundness of Steel Ingots by the Aid of Thermit," were discussed together. Sir Robert Hadfield advocates keeping the top of the ingot hot by the combustion of charcoal with a supply of compressed air blown on to it, placing a layer of cupola slag between the top of the ingot and the charcoal to prevent injurious action and loss of heat by radiation. Dr. Goldschmidt plunges a charge of thermit right down to the bottom of the ingot while this is still in a fluid condition, and, after ebulition, due to violent expansion of gas, has ceased the metal in the mold sinks down and more metal is added from the ladle. Only a small charge of thermit is necessary; about 1 lb. being sufficient for a ton ingot. (Both papers were published in our November issue.)

The discussion was opened by Sir Robert Hadfield, who said that the experience of the past winter in the United States had caused a demand there for a better quality of iron for rail making. He might possibly be wrong in his ideas as to piping and segregation, but he thought it possible to take a block of fluid steel and have no piping at all. If there were no piping there would be no segregation. He had tested this by making a small ingot, 2 ft. 6 in. in length, and keeping the top hot as long as possible. A sulphur print of the metal showed almost entire freedom from segregation, and he believed the same results could be obtained with larger ingots similarly treated. Piping was practically absent in that ingot, which, if made in the ordinary way, would probably have piped considerably.

The president said the subject was most important to steel makers, who were all trying to get the maximum quantity of sound metal from the ingot.

Dr. J. E. Stead agreed that the papers were interesting and valuable, while the authors appeared to have worked on opposite principles, one keeping the top hot and the other the bottom. He thought that the proper principle to work on was to keep the top hot; and really in Dr. Goldschmidt's process the hot metal from the bottom came to the top, and it was equivalent to heating the top. He thought the principle of heating the bottom was wrong, and he would prefer a refrigerator at the bottom and a blast at the top. He suggested that Dr. Goldschmidt should place the thermit nearer the top, and he thought he would thus obtain still better results than the remarkable ones quoted in the paper. They were much indebted to Dr. Goldschmidt for his researches, but he would probably obtain still better results from some slight modification of his process. The accumulated evidence of the last few years proved that in ingots of non-gaseous steel—unless poured very slowly or into molds wide end at the top—the steel remained fluid longer in the lower central axis than in the upper. He submitted a photograph of an etched rail section the central axis of which consisted of almost pure iron. The present explanation of the great purity of the central axis was that the ingot was rolled before the center was quite solid and consisted of crystallites of nearly pure iron mixed with a liquid containing greater part of the metalloids. On passing through the rolls this liquid would be squeezed up into the pipe, leaving behind the solid nearly pure iron. If there was no cavity the liquid might be expelled at the top if the solid metal there were thin, and if it were too thick expansion might ensue at the thin end.

In March of the present year Karl Neu had demonstrated

that rolling ingots where the centers were solid produce blooms with the central axis practically free from metalloids. If Sir Robert's copper method were applied to such an ingot the copper would descend, displacing the impure residual liquid, and, when cold, would be found in the lower central axis, and—according to Sir Robert—would indicate normally unsoundness there, whereas normally that would be the soundest part. That method could be useful only when the steel had quite solidified.

At Cargo Fleet Works Mr. Benjamin Talbot had, during the past two years, experimented on and successfully worked out a process of producing sound ingots. He attains soundness, except as to the central pipe, by means of aluminium or silicon. The ingot is quickly stripped, allowed to stand in the soaking-pit for a short time, and then, with its center still liquid, compressed by a few passes through the cogging mill. Ingots so produced have been found uniformly free from unsoundness, and the parts richest in sulphur, phosphorus and carbon were located in the positions where it was most desirable that anything objectionable should be.

Mr. Benjamin Talbot said he had found it possible to produce rails with a hard face and soft center.

Mr. J. M. Gledhill, of Messrs. Armstrong, Whitworth & Company, remarked that Mr. Talbot's interesting work suggested that the compression system of treating segregation, which they had adopted at their works for large ingots, was the right one. They had recently dealt with a 128-ton ingot, employing a hydraulic pressure of 1200 tons, and except for a little segregation at the bottom the material was entirely homogeneous, and that meant a yield of at least 100 tons of sound metal.

Mr. G. Baker asked what the result of Sir Robert Hadfield's process would be with bottom pouring, which produced a solid crust of steel on which the slag and its covering of charcoal would be placed, and which, one would think, it would be requisite to melt.

Mr. A. S. Keith (Leeds Steel Works) said his firm was making principally tramway rails, of which their output during the last sixteen or eighteen years amounted to 150,000 to 200,000 tons, but for seven or eight years they had been supplying to some of the leading British lines permanent-way rails made from Bessemer basic steel which appeared to give as much satisfaction as other kinds of modern rails. Complaints of broken or defective rails were very rare, although he admitted that his firm's practice was not the most recent. He thought that the use of the processes under discussion would affect the output in small works, and while they continued to supply a rail giving good results and secured repeat orders their practice must be at all events equal to that of more modern works.

Mr. W. H. Hatfield said that Sir Robert Hadfield's methods seemed to satisfy practically all requirements for the production of sound ingots; and his objection was removed by the fact that a sample taken 3½ in. below the surface was virtually of the same carbon content as the ingot. Was there any pulling in these ingots? The disadvantage of Dr. Goldschmidt's process was that after introduction of aluminium by the thermit and formation of a pipe he poured more steel into the ingot. This was a tedious process.

Mr. H. Brearley, with regard to Mr. Baker's question as to the effect of bottom pouring, pointed out that in Sir Robert's process the metal was hottest at the top and consequently in better condition for feeding down than a bottom-cast ingot would be with its cold metal at the top. Sir Robert had embodied and improved two distinct operations which had been in use for a long time in making tool steel, one of which was casting wide end up and the other was the use of charcoal on top of the ingot—a practice of long standing in the production of crucible steel, but without a layer of slag. He was unable to agree with the statement that if there were no piping there would be no segregation, for he had seen perfectly sound ingots of 2 cwt. or 3 cwt. which inevitably showed segregation when polished and etched. He asked whether Dr. Goldschmidt's process introduced a considerable quantity of slag into the ingot.

Dr. Stead produced for inspection photographs supplied by Mr. Talbot to show the necessity for inert material between the charcoal and the top of the ingot. These photographs demonstrated that without such interposition the oxide caused by the blast penetrated even to the bottom of the ingot.

Sir Robert Hadfield in his reply said his view was that cooling should go on from the bottom. Dr. Stead's communication with regard to Mr. Talbot's results was of very great interest, but it was advisable that definite information should be furnished to show the yield of merchantable steel. With regard to the use of aluminium and silicon, they were harmless; then why not use them if sound piping resulted? Twenty-five years ago in a paper before the Institute he showed that a material of very fair ductility could be produced with 1 per cent of silicon, and when 0.2 or 0.3 per cent would insure soundness there need be no fear of using it. With regard to Mr. Baker's practical question as to the crust on the top of a bottom-poured ingot, the heat developed by the combustion of the charcoal would readily melt any half-crusted steel. As to pulling, after the practical production in this way of many thousands of tons of ingots he had not known of more than one or two pulling at the top on account of flash. The amount of heat lost by radiation was small, and the supply of heat at the top not only prevented radiation there but maintained the heat where it was wanted. He was glad that Dr. Stead agreed with his point of feeding from the top rather than adopting means to secure soundness at the bottom. With regard to the time taken for this feeding, the quantity of air used and the charcoal, the extra cost of the process did not exceed 1 shilling per ton. Ordinary cupola blast, at a few ounces pressure, was used.

Dr. Goldschmidt replied that he was sorry that he could not accept Dr. Stead's proposal to use the thermit near the top of the ingot, for he had tried that method many times in many works, and the results were not successful. Dr. Stead had said that he heated the ingot at the bottom, but that was not the case. The rise of temperature resulting from the thermit was not more than 1 deg. C.—practically nothing. He did not regard the reaction in the liquid ingot as thermal, but as mechanical with ebullition which drove all impurities to the top. There was not necessarily any inconvenience in filling up the ingot after the reaction, and two works had adopted the plan of pouring in liquid steel immediately after the reaction and then covering the ingot, but this entailed the loss of a few inches of the ingot. As to the introduction of slag into the ingot, he had given figures in the paper relating to some 20,000 ingots and no slag was found in the metal.

The Royal Mint.

From the forty-second annual report of the Deputy Master it appears that in the year 1911 the total number of pieces struck exceeded 146,000,000: the gold issue was of the value of more than £33,000,000, or rather greater than 2.5 times the average of the previous ten years, and £8,000,000 greater than the issue of any preceding year. The cost of coal gas fuel for melting gold bullion worked out at 5.2d. per cwt.

In the new gold melting house there are ten furnaces. The gas is supplied by a 4-in. main, the air by a 5-in. pipe, and the blower is driven by a 14-hp motor. The silver house has sixteen furnaces suitable for 8000-oz. crucibles capable of dealing with 9.6 tons of standard silver per day, but at present the crucibles are of the 6000-oz. size. An ordinary day's melt in the gold house is 3 tons of standard bullion.

The old atmospheric engine for operating the automatic weighing machines has been replaced by an electric motor. The total number of motors installed is now eighty-nine, with an aggregate of 786 hp. The net profit on the year's working was £374,266.

Cleveland Meeting of the American Institute of Mining Engineers

The 103rd meeting of the American Institute of Mining Engineers was held in Cleveland, Ohio, from Monday to Thursday, October 28 to 31, 1912, and proved to be one of the most enjoyable and successful meetings of the Institute in recent years.

It was the first meeting held under the auspices of the newly formed Iron and Steel Section of the Institute and accordingly the metallurgy of iron and steel was particularly well represented on the program. For the same reason Cleveland, as the center of the Lake Superior iron industry, had been chosen for the meeting, this being the third meeting of the Institute in that city, previous meetings having been held there in 1875 and 1891.

On Monday evening the visiting members and guests were informally entertained at the headquarters in the newly opened Hotel Statler by the local committee, with Mr. D. T. Croxton as chairman and Mr. C. B. Murray as secretary.

On Tuesday morning the professional sessions started, all the sessions of Tuesday and Wednesday being held in the Assembly Room of the Hotel Statler.

The Tuesday morning session was opened by addresses of welcome by Mr. David T. Croxton, president of the Cleveland Furnace Company, and Mayor Newton D. Baker, of Cleveland, who compared in a felicitous little speech some future possibilities of development in the professions of mining engineers and of politicians. A graceful reply was made by the president of Institute, Professor James F. Kemp.

Rail Steel Inspection and Manufacture.

The first paper was read by Colonel **Robert W. Hunt,** of Chicago, on "Recent Developments in the Inspection of Steel Rails," describing the new system adopted by thirty-three railroad companies operating more than 122,000 miles track. Inspectors are placed by the railroads in each manufacturing department of the steel company making the rails, to be on duty during all working hours. These inspectors have to observe all manufacturing operations and if there are serious variations from the details of specifications or from recognized good practice, they have to call the attention of the foremen to what is going on, make a record of the fact, and report it to the inspector in the next department to which the ingot, bloom or rail is passing in the progress of manufacture. The details of the inspectors' observations are also to be reported to the railway company that purchases the rails. This plan of inspection has been cheerfully accepted almost universally by the steel rail manufacturers.

This paper elicited an extended discussion which had as much to do with rail steel manufacture as inspection. Mr. H. D. Hibbard asked about the discard. Captain Hunt replied that there was no uniform practice. The specifications made by the different railway companies are different. While the usual amount of discount is 9 per cent, some railway companies specify that the shearing of the bloom be continued until soundness is assured. In those few cases in which 20 to 25 per cent discard is specified a special charge is made.

In reply to the question of Mr. Charles Kirchhoff whether the manufacturers still give a guarantee of five years Captain Hunt replied in the negative.

In reply to a further question by Mr. Hibbard as to who determines the amount of discard, whether the rail makers or the inspectors of the railway companies, Captain Hunt said that that was a point which was perhaps as much disputed as any other point. It referred to a delicate situation. If the inspector of the railway company would assume the right to say what should be the discard, he would also have the responsibility and the manufacturer would be relieved of responsibility. This is not exactly what the railway companies want. Their inspectors should rather report at once, whenever, in their opinion, any discard has not been sufficient. This goes into the record, and if a rail of that ingot breaks later on they know the reason why.

Mr. Fred Laist asked about the addition of copper to steel rails for the purpose of toughness. Captain Hunt replied that for the Chicago, Milwaukee & St. Paul Railway 10,000 tons of rails of steel containing 0.5 per cent copper had been made by the Illinois Steel Company. The rolling results were quite satisfactory. The copper had been added in the form of copper wire in the casting ladle. This order had been the outcome of very satisfactory results obtained with rails made from ore which contained copper.

Mr. Elwood Haynes, president of the Haynes Automobile Company, said that the chemical process of making the steel was fully as important as the mechanical treatment; for instance, introduction of titanium was just as important as the proper procedure in rolling. For automobile manufacturers the use of nickel and vanadium in steel was very important on account of the ability of such steel to stand vibrations and shocks very well.

Captain Hunt explained that the inspection covers the metallurgical side of steel making as well as the mechanical processes. It is a complete inspection of the metal from the time it is tapped from the furnace until the product is finished. It includes, for instance, additions of various ferroalloys, the condition of the ingot molds, etc., in short the whole history.

Titanium Treatment of Cast Iron.

A paper by Mr. **Bradley Stoughton,** of New York City, gave "Notes on Titanium and on the Cleansing Effect of Titanium on Cast Iron." The paper gives the results, first, of a research into the somewhat extensive literature on titanium, and, second, on a series of original tests extending over a period of more than two years upon the effect of titanium on iron castings. The combined results are summarized as follows:

"1. Steel or cast iron, in which the titanium is properly proportioned, and which has been properly treated, is improved in strength, toughness, and durability against wear, such as, for example, the wear of railroad-rails, of steel and chilled-iron rolls, car-wheels, etc.

"2. These improvements seem to be caused, not so much by the direct effect of titanium on the metal, as by its cleansing influence in removing harmful impurities, such as oxygen and oxides, nitrogen, occluded slags, and perhaps also sulphur. It appears also to reduce segregation, which would contribute to the same end.

"3. In order that its effects may be fully realized, the treatment of steel or iron with titanium must be correctly performed. There are a few simple but essential details to be observed; if they are neglected the best results cannot be expected.

"To illustrate by an example: A series of tests on cast iron was carried on in a German foundry, in which scientific apparatus and instruments were employed, and great care apparently exercised in executing the work, but the titanium treatment was performed without a knowledge of the conditions which should have prevailed, and, as a consequence, the

results were inconclusive. It is as if one should attempt to boil water with the best adapted appliances obtainable; with scientific instruments to measure the temperature and regulate the operations, and with every condition fulfilled except heating the water to a high enough temperature. Obviously, the result would be quite as unsatisfactory at 211 deg. F., as far as boiling water is concerned, as at 60 deg., although the former point it within a hair's breadth of success. So, in adding titanium to iron or steel, if it is put into the slag, instead of the metal, or if opportunity is not given for it to be absorbed and do its work, or if the steel is subsequently allowed to become oxidized, or if the treated metal is cast much too hot or much too cold—if any, or all, of these important details are neglected, we must not expect to get the best results."

From a summary of the results obtained by different investigations the author concludes "that it is entirely possible, by correct treatment with ferrotitanium alloy, to increase the strength of cast iron from 30 to 50 per cent. If this can be done part of the time, then it only remains to determine the correct conditions in order to attain equal success all the time. Some of these conditions I have pointed out, but I do not consider that the problem is completely solved as yet."

In the discussion which followed, Mr. J. E. Johnson, Jr., asked whether titanium reduces the chill. For many purposes in foundry practice the proper chill is important, for instance, for the manufacture of car-wheels and rolls. If titanium reduces the chill it will not be good for such purposes.

Mr. Stoughton replied that if titanium would be used under otherwise unchanged conditions it would reduce the chill. Against this stands the fact that for about 90 per cent of all the rolls and also a good many car-wheels now being made the titanium treatment is employed. But to achieve success it is necessary to change the silicon and manganese contents in order to get the required chill with the titanium treatment. An increase of manganese is necessary. Details of the treatment are kept secret to a certain extent.

President Kemp gave a review of the existence of numerous deposits of titaneferous iron ores, which, if made available, would add very greatly to our iron ore supply. Many of these also contain vanadium and chromium

Cuyuna Iron Ore Range.

Two papers supplementing each other, by Mr. **Walter Barrows,** Jr., of Duluth, Minn., and Mr. **Carl Zapffe,** of Brainerd, Minn., discussed "The Iron Ores of the South Range of the Cuyuna District of Minnesota." In the discussion Mr. D. T. Croxton referred to the successful use of these ores in mixtures of 40 to 60 per cent and even as high as 90 per cent by the Cleveland Furnace Company.

* * *

Case Hardening.

Two papers relating to case hardening were then presented. One discussed the "action of various commercial carbonizing materials," the author being Mr. **Robert R. Abbott,** metallurgical engineer of the Peerless Motor Car Company, and the other paper dealt with "measurements and relations of hardness and depth of carbonization in case-hardened steel," the author being Mr. **Mark A. Ammon.**

Mr. Abbott gave the results of extended tests made with twenty-five different commercial case-hardening compounds. They include pure bone, bone in which the glue has been partly or wholly extracted, bone mixed with other carbonaceous material, partly roasted nuts, husks and kernels of seeds or beans, and finally charred carbonaceous material charged with chemicals. These different materials are designated in the paper by letters from A to Y and the names of the compounds or of the manufacturers are not given. The results of the extended tests are given in numerous tables and diagrams and it is impossible to abstract them.

It is also shown in the paper how to apply the results given in the tables and diagrams for practical purposes. The use to which case-hardened steel is to be put should be the deciding factor in selecting the material with which it is to be carbonized, and also to a less extent the temperature of carbonization should be determined from similar considerations.

The paper by Mr. Ammon on measurements and relations of hardness and depth of carbonization in case-hardened steel points out that the two most widely used methods of measuring hardness are the Brinnell method and the scleroscope.

In the Brinnell method a hardened steel ball is pressed into the steel under a definite load and the area of the resulting depression is measured. In the scleroscope method a small weight carrying a diamond point is dropped through a glass tube upon the steel and the amount of rebound is taken as proportional to the hardness.

When applied to case-hardened steel both methods should not be expected to give the same results because the scleroscope method gives almost exclusively the surface-hardness, and the condition of the material below the surface has but a slight bearing upon the hardness number. The results given by the Brinnell method should, however, be the exact opposite; for the depth of penetration of a ball pressed into the steel would be dependent to a large extent upon the condition of the material below the surface.

The author has made an investigation into the hardness of case-hardened steel by means of a combination of these two methods. The results of the investigation are given in a series of tables and twelve diagrams and certain facts shown in these results are summarized. The knowledge gained by this research work has formed the basis of a system of testing carbonized parts for depth of carbonization and efficiency of the heat treatment.

The two papers were discussed by Messrs. Hibbard, Johnson, and Stoughton. A unanimous vote of thanks was passed to the automobile companies for their liberal policy in permitting the publication of the information contained in the two papers.

* * *

Ruff's and Wittorff's Carbon Iron Equilibrium Diagrams.

A paper by Professor **Henry M. Howe,** of Columbia University, points out that "Prof. Ruff's most illuminating paper describing his extremely valuable investigation of the carbon-iron equilibrium diagram assigns definite temperatures to certain very important lines in the diagram," viz.: the eutectic temperature and the "near eutectic" temperature, but without indicating clearly enough the reasoning which warrants these assignments. Prof. Howe, in his present paper, indicates the apparent gaps in the reasoning.

He concludes that the unexplained variations in the cooling curves are very great, that the two series of observations on this point by Gutowsky do not agree; and that the rate of graphitization is very capricious. Graphitization continues at temperatures far below those to which Prof. Ruff seems to confine it. There is difficulty in reconciling the Gutowsky and the Ruer and Iljin lines with the assumed dominance of the "bodenkoerper," all of which seem essential premises underlying Prof. Ruff's reasoning. "In view of these facts the data as to arrest temperature and graphitization in the single Gutowsky series used by Prof. Ruff seem wholly insufficient for a firm foundation on which to base calculations as to the equilibrium position of the eutectic temperature."

Mr. **Bradley Stoughton** then presented a translation in abstract, prepared by him with the aid of Mr. Sidney Marcus from the Russian original of N. M. Wittorff's "Preliminary Investigation of Primary Crystallization and Subsequent Physico-Chemical Permutations in Iron-Carbon Alloys Containing More Than 4 per cent Carbon." Mr. Stoughton showed that this paper is of great interest in connection with Howe's paper.

The result of Wittorff's study is to greatly extend our knowledge of the hypereutectic alloys of iron and carbon, and to add several significant lines at the right-hand side of the diagram originally drawn by Bakhuis-Roozeboom, and developed by Roberts-Austen, Benedicks, Carpenter & Keeling, Upton, Goerens, and others.

The two papers of Professor Howe and Mr. Stoughton were discussed at some length by Messrs. J. E. Johnson, Jr., Henry D. Hibbard, Bradley Stoughton, R. H. Sweetser, and James F. Kemp, and it is particularly noteworthy to record that such distinguished blast furnace men as Messrs. Johnson and Sweetser emphasized the value of equilibrium diagrams for practical furnace operation. This concluded the meeting of the morning.

The afternoon session was also held in the Statler Hotel and the first paper was presented by Mr. Sweetser.

Blowing in a Blast Furnace.

The object of this paper by Mr. **R. H. Sweetser,** of Columbus, O., is to put on record a blowing-in practice that has gradually developed to the point where the results are sure, safe, and satisfactory; and also to bring into discussion several variations that are questionable.

"Drying-Out the Furnace.—As soon as a furnace-lining is completed it should be thoroughly dried out, whether it is to be blown-in soon or not; and the longer it is dried, the better for the furnace. At least two weeks is desirable; but good results can be had with 10 days of firing. The crudest and least desirable method of drying is to build a wood fire in the bottom of the furnace, throwing the wood in through a tuyere-arch, and using the iron-notch for draft. The accumulation of wood-ashes on the hearth-bottom keps the brick from heating thoroughly, and considerable time is lost in removing the ashes.

"An effective and easily-controlled method is to build a 'Dutch oven' outside one of the tuyeres and use coke for fuel. This method may be intermittent or continuous, a desirable feature, since sometimes it is necessary to pack plates or coolers on the day-turn, and dry-out on night-turn. Coal could be used for fuel, but coke is cleaner and gives a hotter fire.

"The 'Dutch oven' can be built at the iron-notch, but often it is necessary to fit up the iron-notch gun and the gun-bar; and then the oven would be in the way. With the oven at a tuyere-arch, the hearth-bottom can be well heated by a wood fire built right in the casting-trough; the strong draft will draw the heat through the iron-notch. Fig. 1 shows a simple oven for a tuyere-arch; if used at the iron notch, the neck of the flue would have to be turned downward.

"Pipe for the Iron-Notch.—In order to burn completely all the kindling wood below the tuyeres before the slag falls into it, and also in order to heat up the hearth bottom thoroughly, it has long been customary to place an iron pipe, 3 or 4 in. in diameter and about 10 ft. long, in the iron-notch. This pipe should project from 6 to 18 in. inside the furnace wall. If the hearth bottom is much below the level of the iron-notch there is no need for the pipe to project much beyond the inside of the walls, but if the hearth level is almost up to the bottom of the iron-notch, the pipe should project farther. In either case the part of the pipe inside the furnace should be thoroughly covered over with stiff clay, so as to protect it from any molten slag or iron.

"The pipe should be in the center of the iron-notch, and as nearly level as possible. Near the outer end of pipe there are four holes, 0.75 in. in diameter, in which to insert hooks for pulling out the pipe when the time comes. As soon as the blast is on the furnace, the gas will come through the pipe out into the iron trough, where there should be a wood fire to ignite it immediately. As the volume of gas increases, the gas flame at the end of the pipe gets hotter and roars more, but does no harm. It is my practice to let this gas burn at the iron-notch for four hours after starting the blast, and then to pull the pipe and shut the notch.

"Shutting the iron-notch is one of the critical stages of blowing-in; but if everything is in readiness the work can be done in less than three minutes, with an iron-notch gun and a steam cylinder attachment on the gun bar. The iron pipe should be turned in the iron-notch so as to loosen the clay; this can be done by inserting a bar or hook in one of the four holes near the outer end of the pipe. A quick jerk on the hook will pull the pipe clear of the iron-notch, and then the gun is swung around quickly and forced into place with the steam cylinder.

"Filling the Wood.—The placing of the kindling wood in the hearth and bosh is such an important part of blowing-in a blast furnace that the superintendent or his assistant usually gives personal attention to each detail, staying inside the furnace to see that every stick of wood is properly placed. The simplest method (as is often the case in furnace practice) of putting wood in the hearth has proved to be the best in every way. David Baker taught it to me twenty years ago, and he doubtless learned it from some old furnace man at Steelton. No fancy scaffold is made, but cord sticks are packed as tightly as possible, in alternate layers at right angles to each other, from the hearth bottom up to the level of the bottom side of the tuyeres. The wood is all passed into the furnace through one tuyere-arch with the cooler left out.

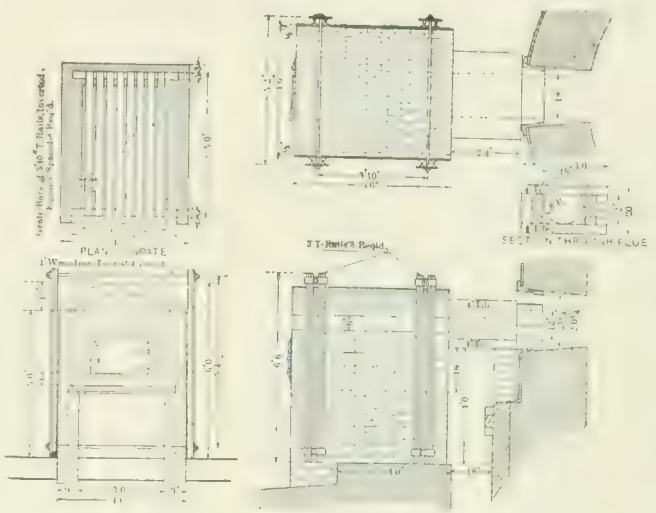

FIG. 1.—"DUTCH OVEN" FOR DRYING OUT BLAST FURNACES.

"At the Algoma Steel Company I first used the 'Algoma cones' at the tuyeres. These are made by placing dry building laths in front of each tuyere with the inside ends coming to a point towards the center of the furnace, and the other ends placed all around the nose of the tuyere. The spaces between cones are filled up with short sticks, split cord sticks, and any dry kindling available, and the whole surface is leveled with the exception of a place about 3.5 by 4 ft. in front of the tuyere where the wood is passed in. A vertical shaft about 10 ft. high is here made by nailing four posts (4-in. x 4-in. sticks or small saplings) in position. Two posts will be close to the wall on either side of the tuyere-arch and the other two will stand about 4 ft. from the wall. Cord sticks are then piled on end all across the furnace and around the shaft; then a second tier of cord sticks is placed in as tightly as possible. Usually the top of this second tier will be below the top of the bosh, and cord sticks are laid against the walls all around the furnace to protect the brick and plates from falling stock.

"When this is done enough wood is passed inside the furnace and up the shaft so that when the last man 'backs out' he can fill the shaft solid with wood. All the men except two go

outside, and the tuyere cooler is set in place. The two men pack the cooler from inside with clay, and place the kindlings in front of the tuyere, then 'back out' up the shaft. The wood is then thrown down into the shaft and packed in solid, and the two men are hoisted out at the top of the furnace in a boatswain's chair.

"Filling with wood in the above manner accomplishes perfectly three things desired, namely: the heating-up of the hearth without leaving any appreciable amount of ash; the ignition of the coke charge and the starting of the smelting process; and the movement of the stock with such gentleness that the settling on top, within two hours after the blast goes on, cannot be detected except by using the gage rod.

"Coke on the hearth bottom and built-up scaffolds do not usually attain all these points, and do not produce good iron on the first cast.

"Filling the Stock.—On top of the wood, regular charges of coke with just enough limestone in each charge to flux the ash of the coke, are dumped in the usual manner. The size of this coke 'blank' is more often too large than too small. I am indebted to Frank P. Howe, of Philadelphia, for learning the advantages of using about 20 tons of coke instead of 40 or more. The next set of charges has an equal amount of coke plus cupola slag and enough limestone to flux the coke and slag. Then follow the ore charges with gradually decreasing amounts of slag. Charcoal furnace slag is excellent for the slag charges, but is usually harder to get than clean cupola slag. If the slag is not granulated it should be broken up to about 2-in. size. A good volume of easily melted slag is needed to fill up the hearth and receive the first iron that comes down.

"A charging schedule that has worked successfully several times is as follows:

Charges.	Coke. Pounds.	Limestone. Pounds.	Cupola Slag. Pounds.	Ore. Pounds.
6	6510	730	0	0
6	6510	4000	4000	0
5	6510	4300	4000	1800
5	6510	3600	3000	2400
5	6510	3000	2000	3600
5	6510	3300	2000	5000

"These materials filled a 75-ft. x 18-ft. furnace.

"The first five charges after the blast went on had 1000 lb. of slag and 6400 lb. of ore; then the slag was omitted and the ore gradually increased to full burden.

"When the stock gets within about 20 ft. of the top, it is a good plan to take measurements of the surface of the stock, and to make careful observations of the distribution; at this time gage rods should be tested as to accuracy in reading.

"Putting the Blast On.—I believe in putting the blast on at once, and using hot blast to light the furnace whenever previously heated stoves are available. If the volume of blast is increased properly the furnace will not 'hesitate,' but will move off easily, and the first slip will be indefinitely postponed. If the stoves have not been previously heated with gas, then red-hot rods are thrust in through the tuyeres to light the kindlings.

"If the furnace is a single stack and the gas flues are cold and empty, the method of 'bringing down the gas' is different from the way when there are one or more furnaces in blast and delivering gas into the same gas mains.

"When the blast is turned on a single stack, both bells and the top bleeders are left open for a while and not closed until there is a steady and voluminous flow of gas at the top of the furnace. The big bell, and then the little bell, are closed, and all the gas goes out at the bleeders. All gas burners on stoves and boilers are tightly closed, and all fire is kept away from dust catchers and cleaning doors. The gas mains are gradually filled with the dense white furnace gas by partly closing the bleeders. At the farthest end of the gas main, gas is allowed to escape through a valve or a cleaning door, so as to expel all the air in the mains. When gas is leaking through all the cracks of doors and burners, and there is pressure inside the gas main, the last gas burner under the farthest boiler is slowly opened, and the gas is lighted by the fire on the boiler grate. The bleeders are then closed so as to force all the gas into the mains. By having the mains full of gas at a pressure of [illegible] inches of water, the danger of explosions is averted. The very dangerous quality of the blowing-in gas is shown by the analyses I made and recorded in the *Transactions* of the American Institute of Mining Engineers, Vol. 28, page 608 (1898), but all trouble can be avoided by proper handling of the gas. Great care must be taken not to open gas burners faster than the volume of gas will allow, as the volume and pressure increase, the burners at the stoves can be opened.

"In the cases of 'twin' furnaces all these precautions can be omitted and the gas from the new furnace can be soon turned into the gas mains by closing the bells and bleeders. Of course, the gas valve between the new furnace and those already in blast must be opened just before the blast is turned on.

"I will not attempt to give in exact cubic feet the amount of blast that should be blown during the first hours of blowing-in; but the volume at all times during the first day or two should be sufficient to prevent must blast pressure on account of 'hesitating' in the settling of stock. While the wood is burning the blast-volume should be sufficient to prevent gas from coming back in the tuyeres by reason of the pulsations of the engines. I usually start with 25 per cent of the normal blast.

"The First Flush and First Cast.—The first flush is anxiously looked for in ten or twelve hours after the blast goes on. Where slag is used in filling the furnace, a considerable amount should be flushed out before any attempt is made to open the iron-notch.

"In opening the iron-notch for the first time there should be no trouble whatever, providing the keeper drills in on the level and through the soft clay that fills the hole left by the 4-in. pipe. Sometimes a big tapping bar is driven into the soft clay as soon as the iron-notch is shut for the first time, as described above. But I have found that there are several disadvantages in this and now prefer to leave the bar out.

"The furnace blown in Aug. 17, 1909, had very hot stoves to start with, and the blast-temperature exceeded 1400 deg. On this account the blast-volume was increased more rapidly than usual, and the first cast (34,620 lb.) was only thirteen hours after the blast went on.

"The furnace blown in Aug. 20, 1912, had no bottom brick on top of the salamander that had been left in, and on account of the increased depth of hearth the cinder was longer than usual in filling up the cinder notch."

In the discussion which followed Mr. Johnson referred to the danger of explosions in bringing down the gas. Mr. Dougherty had taken out a patent for overcoming this difficulty by inserting a cushion of steam in the downcome to prevent the dangerous mixture of gas and air. But this had been used years before the patent was taken out, so that anybody may use it.

Cobalt-Chromium Alloys.

A paper by Mr. **Elwood Haynes,** president of the Haynes Automobile Company, of Kokomo, Ind., gives the results of his very interesting researches on the properties of alloys of cobalt with chromium and other metals.

The preliminary fusions were made in graphite crucibles by means of a furnace operated by natural gas, and later in crucibles of a special composition, not only to avoid the contamination of the metal by carbon from the crucible, but also because they proved more reliable under long-continued heating.

"The metal tungsten alloys readily with chomium and cobalt in all proportions. When added in small quantities to the cobalt-chromium alloy, it seems to have little influence on the properties of the combination but if the proportion rises to 2 or 3 per cent a notable effect is produced. Generally speaking, the cobalt-chromium alloy becomes harder and more elastic, especially if it contains a small amount of carbon, boron, or silicon.

"The following experiment shows the effect of melting the alloy in a graphite crucible: 90 g. of cobalt, 6.3 g. of tungsten, 18 g. of chromium, together with a small quantity of calcium silicide, were introduced into a graphite crucible. The resulting alloy was very hard, and the crucible much eroded on the inside. The bar could be slightly flattened at one end, and after being made into a cold-chisel, showed remarkable qualities. It would not only scratch glass, but also quartz crystal. It was quite tough at ordinary temperatures, and would cut small chips or shavings from a piece of stellite. At a bright yellow heat it showed signs of fusion, and became covered with a skin of oxide.

"An alloy was made by melting the following in a special crucible: cobalt rondelles, 80 g.; chromium, 20 g.; tungsten, 7 g.; calcium silicide, 10 g.; calcium carbide, 5 g. As soon as the above were melted, the crucible cover was removed, and 15 g. of an alloy of cobalt and boron was introduced. The crucible lid was then replaced and the heating continued. A heavy, thick slag formed, which was removed before pouring the metal. The resulting bar was very hard and elastic, but only drew slightly under the hammer, and then broke. A cold-chisel made from the cast metal cut iron readily. The bar was broken up and remelted with about one-third of its weight of an alloy of cobalt, chromium, tungsten and carbon. The result was a fine-grain alloy which was very elastic and would draw out to a considerable degree under the hammer without checking. Its elastic limit must have been very high, since when it broke, the pieces were thrown violently.

"Taking the alloy of chromium and cobalt as a basis, and holding the proportion of chromium at 15 per cent of the entire mixture, it was found that the alloy gradually increased in hardness with the percentage of tungsten. When the quantity of tungsten rises to 5 per cent. the alloy becomes distinctly harder, particularly when forged under the hammer. When the tungsten reaches 10 per cent, the metal still forges readily, and a tool formed from the alloy takes a fine cutting edge. This alloy is suitable for both cold-chisels and woodworking tools.

"When the tungsten rises to 15 per cent, the metal can still be forged, but great care is necessary in order to avoid checking. This alloy is considerably harder than that containing 10 per cent of tungsten, and is excellent for cold-chisels. When the tungsten rises to 20 per cent, the alloy is still harder, and can be forged to a small extent. It makes good lathe-tools for cutting steel and other metals at moderate speeds. When the tungsten rises to 25 per cent, a very hard alloy results, which cannot be forged to any extent, but casts readily into bars which may be ground to a suitable form for lathe-tools.

"These tools have shown great capabilities, particularly for the turning of steel, since they are very strong and retain their hardness at speeds which almost instantly destroy the cutting-edge of a steel tool.

"The tungsten may be still further increased to 40 per cent, and the alloy will retain its cutting qualities, and for turning cast iron this alloy answers even better than that containing 25 per cent. When the tungsten reaches 40 per cent or more, the alloy becomes so hard that it will not only scratch glass but will readily scratch quartz crystal. A small drill made of this material drilled a hole through the wall of a glass bottle without the addition of any liquid or other lubricant.

"A ⅜-in. square cast bar, when ground to a suitable edge, was set in a tool-holder attached to a lathe. The workman who had operated the lathe had been able to turn to form 26 cast-iron wheels in 10 hours with a steel tool of the same size. The stellite tool turned 49 of these wheels to form in the same time. The steel tool was ground 50 times during the operation, while the edge of the stellite tool was dressed slightly by a carborundum whetstone after its day's work.

"A set of steel cutters, placed in the boring head of a cylinder-boring machine, was able to bore from 27 to 28 holes in 10 hours. These cutters were replaced by others made of stellite, which performed the work in 3 hours and 20 minutes, or a little more than one-third of the time. Not only was the speed of the mill doubled, but the feed also, and notwithstanding this severe ordeal, the stellite cutters were only slightly worn, while it would have been necessary to re-grind the steel cutters at least two or three times for the same service at slower speed.

"Some remarkable result were obtained in the turning of steel on the lathe. For example, a cylindrical bar of annealed nickel-chrome steel, about 2.5 in. in diameter, was placed in a lathe and turned with a steel tool at about as high a speed as the steel would permit without 'burning.' The steel tool was then replaced by one of stellite, and the speed at the same time increased to 2⅔ its former speed. The stellite tool retained its edge under these severe conditions and produced a shaving weighing 1 2/10 lb. in 30 seconds. Just what the effect of the alloy will be in machine-shop practice is at present somewhat difficult to determine. In my opinion, however, it will not fully supersede high-speed steel in the machine shop, but in cases where rapid work is the main consideration, it will, doubtless, replace high-speed steel.

"When molybdenum is added to a 15 per cent cobalt-chromium alloy, the alloy rapidly hardens as the molybdenum content increases, until the content of the latter metal reaches 40 per cent, when the alloy becomes exceedingly hard and brittle. It cuts keenly and deeply into glass, and scratches quartz-crystal with ease. It takes a magnificent polish, which it retains under all conditions, and on account of its extreme hardness, its surface is not readily scratched. When 25 per cent of molybdenum is added to a 15 per cent chromium alloy a fine-grained metal results, which scratches glass somewhat readily and takes a strong, keen edge. Its color and luster are magnificent and it will, doubtless, find a wide application for fine, hard cutlery. It cannot be forged, but casts readily, and its melting point is not abnormally high.

"If carbon, boron or silicon be added to any of the above alloys they are rendered much harder, though their effect is not always desirable, since they tend to render the alloys more brittle.

"If either tungsten or molybdenum is added to a cobalt-chromium alloy containing 25 per cent of the latter metal, the hardness of the alloy is rapidly increased. When the percentage of tungsten, for example, reaches 5 per cent, the alloy can be readily forged, and forms an excellent combination for woodcutting tools, such as chisels, pocket-knives, etc. When molybdenum is added to the same mixture of chromium and cobalt, much the same effect is produced, though, generally speaking, a smaller quantity of molybdenum is required to produce a given increase in hardness. In some instances I have found it advisable to add both molybdenum and tungsten to the cobalt-chromium alloys. Generally, the color and luster of these alloys, after polishing, are magnificent and they seem to resist atmospheric influences equally as well as the binary alloy of cobalt and chromium."

Mr. Haynes had exhibited a number of most interesting samples of various products made from his alloy, to which he has given the trade name stellite. He emphasized that some of the alloys are almost immune to chemical influence, for instance, absolutely immune to nitric acid and almost so to hydrochloric acid.

In reply to questions as to cutting qualities of stellite as compared with high-speed tool steel, Mr. Haynes said that the superiority of the stellite tool is its ability of cutting more rapidly rather than cutting harder stuff. Further, the stellite tool stands up better; it is not to be ground so often as the best high-speed tool steel. The tensile strength of stellite varies greatly like that of steel.

Stellite is, however, much more expensive than high-speed tool steel on account of the higher initial cost of the starting materials, but for purposes where rapid work is an important consideration the savings which can be obtained with stellite will compensate the higher cost.

By-Product Coke Ovens.

There were three papers on this subject presented, the authors being Messrs. Blauvelt, Andrews and Lucas respectively, and a long and animated discussion followed in which Dr. Schniewind and Mr. Blauvelt were the chief speakers.

Mr. Blauvelt's Paper on Coke.

Mr. **William Hutton Blauvelt,** of Syracuse, N. Y., in his paper on "Manufacture of Coke" referred to the coals suitable for coking, the best cell structure of coke for blast furnaces and for foundry purposes and the detrimental effect which oxygen in coal has on the coking qualities.

For many years the bee-hive oven was the standard for coke making, and has remained the standard in England and America long after its practical disappearance from continental Europe. There are several reasons for this. In England, the Durham coal, and in America, the Connellsville coal, are remarkably well suited to the conditions of the bee-hive oven, so that the best quality of coke could be produced without difficulty and with relatively good economy. In America the bee-hive oven had certain economic advantages. It is quickly built and at relatively low cost and the labor required for operation is of low grade. It can be put out of run at relatively small loss during periods of industrial depression and can be started up again with ease after a shutdown. These qualities adapted it to the fluctuating and changing conditions which for many years surrounded our iron industry. But the iron industry has become more stable; and moreover, the coals best adapted to the bee-hive oven are growing scarcer, especially with the exhaustion of the Connellsville field.

From 1907 to 1911 there was an increase in by-product coke of 40 per cent, and a decrease in bee-hive coke of 22 per cent, so that in 1911 the tonnage of by-product coke was 28 per cent of the bee-hive tonnage. By-product plants now under construction and in contemplation will greatly increase the present output.

The bee-hive oven is usually located at the coal mine. The by-product oven is usually located, in this country at least, at the point of consumption of the coke or at some center of distribution. This freedom of choice of location of the by-product oven has a number of advantages. One advantage is that it permits a convenient assembly of several kinds of coal at the ovens because mixing has become quite popular.

There has been much discussion regarding the relative cost of bee-hive and by-product oven plants. It is difficult to make an exact comparison, since the functions of the two types are quite different. For example, in many cases the cost of a by-product oven plant includes a large expenditure for coal storage of several hundred thousand tons in order to take advantage of water freight rates. On the other hand, bee-hive plants are often built in connection with coal-mining plants and utilize a share of power plant, water supply, etc., without having these necessary adjuncts included in their capital account. Careful inquiry into the actual cost of bee-hive oven plants shows that to build such a plant complete in every respect, and in the best manner, including all the equipment besides the ovens and their immediate appurtenances, such as electric power plant, water supply, railroad approaches and sidings, coal handling, etc., would require an expenditure of about $950 per oven.

The P. S. Geological Survey report for 1911 gives the tonnage of coke produced per active bee-hive oven at 466 tons per annum. This figure is, doubtless, low for the best bee-hive ovens; 675 to 700 tons per annum will, perhaps, represent fairly the average output per oven of a modern bee-hive plant. An average of these figures gives a plant cost of $1.38 per ton of coke produced per annum.

A by-product oven plant of say 80 ovens, complete in every respect, and built in the best manner, would produce say 425,000 tons of coke per annum from an average coal and would cost say $1,100,000. Of course, this figure would be varied by local conditions. This is equal to $2.58 per ton of coke per annum. On the basis of these figures a by-product plant costs 86 per cent more than a bee-hive plant.

The owner of a small acreage of coking coal might perhaps well hesitate before making the larger investment, as compared with a simple plant of bee-hive ovens, but, as a general proposition, there hardly seems to be a question as to which style of oven is the better investment. Much of the additional cost of the by-product plant per unit of coke produced is, of course, due to the installation of the apparatus and buildings for the recovery and treatment of the by-products. Other important items are provisions for coal and coke storage, thereby assuring uniformity of operation and greater ability to maintain uniform deliveries. Moreover, a by-product plant is built for a longer life than a bee-hive plant. Eight years may perhaps be considered as a satisfactory life for a bee-hive oven plant, while double this term, or 16 years, would be several years within the life of a well-built by-product plant.

America now leads Europe in output of plant, size of oven, and rate of coking. In the early days of the by-product oven in America the capacity of the oven was about 4.4 tons of coal per 24 hours and twenty-five ovens were considered about the right number for one crew of men. Modern ovens have a capacity of as much as 20 tons of coal per oven per day, and by the introduction of more machinery and more efficient design, the number of ovens handled per man is also increased greatly. The rate of coking is one point in which American practice has gone ahead of Europe.

Retort ovens have been built of various widths from about 14 in. to about 30 in., to suit various ideas of the designers, and various coals; but, within limits, the rate of coking per inch of coal does not vary materially with the width of the oven. Not many years ago the best rate of coking was about 1 in. of oven width in 90 minutes; that is, a 16-in. oven which is coked in 24 hours. To-day there is more than one type of oven which is coking regularly at the rate of from 50 to 55 minutes per inch of oven width. This increased rate was made possible partly by better control of the heating system and partly by the adoption of silica brick in the oven construction.

During the past few years special study has been given to the heat economy of the retort oven and material advance has been made. From most American coals more gas is produced than is necessary for heating the ovens. The conditions under which it is to be operated have an important bearing on the design of an oven plant.

It may be said that there are three general conditions: *First,* where there is not sufficient market to dispose of the sur-

plus gas. In this case the design of oven should be very simple. Any complication of the design for preheating the air should be avoided, since satisfactory coking temperatures can be maintained with cold air, if economy of gas is no object. Steam for the operation of the plant should be raised by burning the surplus gas under simple boilers.

The *second* condition is where there is a market for the gas, perhaps for industrial purposes, but at a low price, and the cost of coal and labor is relatively high. In this case the oven design should provide for partial heating of the air, with proportionate economy of gas for heating the oven, so that the remaining heat in the waste gases is just about sufficient to furnish the steam required for the plant.

In the *third* case the gas is salable at a good price, so that it is desirable to recover the maximum amount for sale. Under these conditions an oven design is justifiable which, while more costly in construction, is most economical in heat consumption. The air is heated in the best form of recuperators or regenerators to 1000 deg. or 1100 deg. C., and the waste gases go to the chimney too cool to be of value. Under these conditions coal and coke breeze are used for producing the necessary steam. Whether steam is used for the production of power, as well as for the distillation of ammonia, heating, etc., or whether the power is generated by gas engines, depends upon the relative market value of coal and gas.

The following tabulated data show in a general way what may be expected from plants designed for the three conditions mentioned above. The figures show the results per ton of coal coked. They represent average conditions and average coals, and, of course, would be modified by special conditions.

Type of Oven.	Fuel gas, per cent.	Surplus gas, per cent.	Steam produced, pounds.
No air preheating	70	30	1050
Partial air preheating	60	40	800
Maximum air preheating	40	60	0

The tendency of modern retort construction, especially in America, is towards the highest economy of heat, even at the expense of simplicity and economy of construction. The proper heating of a retort oven is not a simple problem. It consists essentially in the distribution of heat from burning gases over the side wall of the oven, which presents an area from 35 to 40 ft. long and from 8 to 12 ft. high. The temperature over this entire area must be always under accurate control. When operating for maximum output the temperatures must be held at a point not far below the softening point of the brick, and since the oven chamber is wider at one end than at the other, to permit easy discharge of the coke, the heats must be modified accordingly, so that the whole charge may be coked in the same time. It is also often desirable to maintain a somewhat lower temperature in the upper part of the oven. The combustion of the gas with air which has been preheated to, say 1100 deg. C., as it is in the latest regenerator ovens, produces a theoretical flame temperature of about 2400 deg. C. The actual temperature produced would be much above the melting point of the best refractory brick, and while economical operation demands a full utilization of the best temperatures attainable, the walls of the combustion flues must not be injured nor must there be "hot spots" or "white ends" that will overburn the coke in the adjacent part of the oven chamber.

Fig. 2 shows diagrammatically the application of the heat in the different types of ovens. *A* indicates the combustion flue system of any retort oven with its regenerative chambers below. *B* and *C* show applications of this general arrangement as adopted by oven systems employing vertical flues. *D* shows the application to the horizontal-flue ovens of the series type. *E* a horizontal type where all the flues are in parallel. *B*, *C*, and *D* represents the methods generally adopted in commercial ovens.

In the former type, or the vertical-flue oven, the gas and air are mingled and burned in horizontal flues at the bottom of the vertical flues, the burning gases distributing themselves and passing up one-half the vertical flues and down the other half, as indicated in the sketch; or gas and air are led separately to the bottom of each of the vertical flues, where they are mingled by properly arranged nozzles and burned as they pass upward. In some ovens a combination of these different methods is adopted.

HORIZONTAL FLUE-OVEN DESIGN.

D illustrates the horizontal series-flue regenerator oven; and, as Mr. Blauvelt has had more experience with this type, he discusses somewhat in detail the principles of its operation. All of the air required for the combustion is passed through the

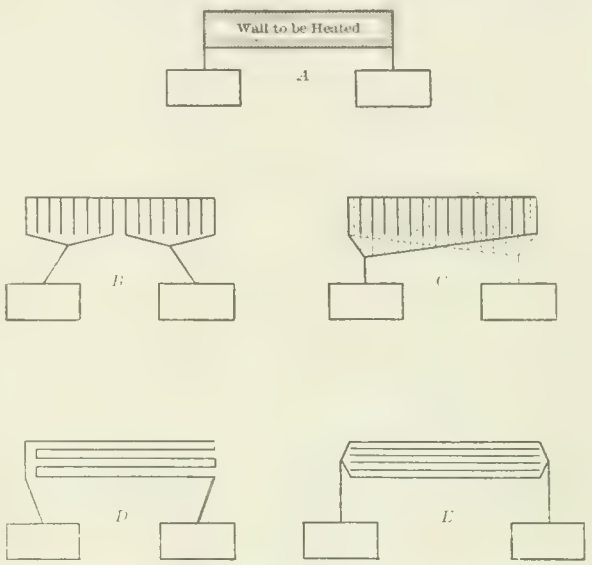

FIG. 2.—APPLICATION OF HEAT IN DIFFERENT TYPES OF COKE-OVENS.

entire flue system, first from above downward, and then from below upward, as the regenerator system is reversed. The heating gas is admitted at the end of the flues, usually in four or five places, as may be required.

This method seems to give a maximum of simplicity. The flow of gas is automatically reversed in the flues themselves by the change in the current of air. Every flue may be conveniently inspected from end to end by a man walking along in front of the ovens, and the gas admission at each point is directly under his hand, so that there is no excuse for failure to immediately observe and correct any tendency to unequal heating.

The distribution of the heat throughout the flue system is made remarkably uniform by this process. This is partly due to the comparatively high velocity of the gases sweeping through the flues and to the fact that the gas is burned either in a large excess of highly heated air, or else in a mixture of air and products of combustion. The advantages of the presence of products of combustion in the combustion chamber, where it is desired to obtain a distribution of heat, have been clearly shown in other combustion processes, such as the Doherty system of producer operation, for example.

In beginning the experimental work leading up to the present method of operation, while it was recognized that the presence of a large volume of air, together with products of combustion mixed with the burning gas, was an important factor in distributing the heat with uniformity, yet it was feared that passing the entire volume of air through all the flue system might seriously increase the friction and make the maintenance of sufficient draft a difficult matter, even though the total amount of air admitted could be accurately proportioned so that it would be just sufficient to burn all the gas.

Hence, an oven was designed with the flues in parallel, in order to reduce the velocity of the gas currents, following the principle of the vertical-flue type. It was found, however, that the velocity of the gases passing through the flues did not produce material friction loss, but that most of the friction arose from eddies in the currents at the ends of the flues; and by a suitable modification of the structure at these points it was easy to keep down the draft required to a reasonable amount, while maintaining the velocity of flow that was so effective in securing uniform heats.

This method of handling the gases through the flues in these series-flue ovens has, therefore, two advantages. It is effective in distributing the heat uniformly from one end of the flue to the other, and at the same time the higher velocities effect a more efficient transfer of heat through the flue wall. The effect of velocity of travel on the transfer of heat through walls has also been shown very clearly in a series of experiments on steam boilers made by the Engineering Experiment Station of the University of Illinois.[1] It will be remembered that these tests were undertaken to determine the relation of heat transmission to velocity of circulation in the steam boiler. They show very clearly the important effect of velocity flow on rate of heat transmission, and from the deduction therein set forth it would appear that the same conclusions may be drawn in the study of our problem.

Having obtained by these means such an effective distribution of the heat, the arrangement of gas admission to the flue system makes it easy to control the temperature of the whole system under the severe conditions described above. The result is that in this type of oven the heat is remarkably uniform from end to end, hot or cold spots are practically unknown, and the control of the temperature is much easier than ever before.

The temperatures maintained in the flue system depend, of course, upon the rate of coking it is desired to maintain. They usually run from 1000 to 1250 deg. C., or somewhat higher. The temperature at the point of entrance of the heated air is controlled by the admission of the proper supply of gas, and additional gas is introduced at other points in the system in order to make up for the heat transmitted into the oven chamber, or to augment the temperatures as may be necessary in preserving the proper relations of heat in the different parts of the system. The periodical reversal of the gas currents prevents any tendency to inequalities which might otherwise develop.

The perfecting of this system makes the regenerative retort oven quite as simple and easy to operate as the recuperative oven, and at the same time secures the maximum heat economy. There is only one reversing valve on each oven block, by which the currents of air and products of combustion are reversed through the system, and this may be easily operated by a simple mechanical device with time control. All the other advantages of the older system, of simplicity and reliability of operation, are maintained.

This type of oven utilizes the principle of a heavy wall between each two oven chambers. This wall occupies some room and, therefore, more space per unit of production, yet it has several material advantages. It supports the main body of the oven structure and carries, without difficulty, the weight of the heavy charging cars, which, when loaded, may weigh more than 20 tons. It permits that part of the oven structure which is subjected to the highest heats to be readily repaired, or even entirely replaced, without effecting the integrity of the main structure and also without stopping adjacent ovens. Another value of these intermediate walls is that they act as a reservoir of heat. They accumulate heat during the coking process and when fresh coal is charged they come to the assistance of the burning gas and help the oven pick up its heat and maintain a coking temperature.

While the earlier by-product oven plants were simpler in design and equipment, the modern plant is almost entirely mechanically operated, and electrically driven machinery has taken the place of most of the hand labor.

BY-PRODUCT

During the development of the by-product oven in the last few years much study has been given to increasing the effectiveness and economy of the apparatus for recovering the by-products. This recovery consists essentially in the cooling of the gas, which causes the condensation of much of the tar vapor and water vapor, which latter brings down with it part of the ammonia. After cooling, the gas is scrubbed in contact with water, sometimes by passing it through tall towers through which water is showered, sometimes by bubbling through water in a series of shallow pans, or by other methods; the object in all scrubbing processes being to bring the gas in contact as intimately as possible with wetted surfaces, to take advantage of the strong affinity of water and ammonia.

The weak ammonia liquor produced in these processes is distilled by steam, producing either the ammonia liquor of commerce, or, by more refined operations, the purer grades of ammonia. If the ammonia gas from the stills is passed into sulphuric acid, ammonium sulphate, one of the most important artificial fertilizers, is produced.

Much work has been done lately on what are known as direct processes for the recovery of ammonia. In all these processes the gas is passed directly through a bath of sulphuric acid, thereby turning the ammonia into sulphate. Several such "direct" processes have been worked out, the difference being principally in the method employed for the removal of the tar from the gas, which is then bubbled through the sulphuric acid bath; the ammonium sulphate settles out and is removed, and the gas is ready for further treatment. At this point the light oils are removed or the gas is sent direct to the point of consumption. Several methods have been advocated for the utilization of the sulphur in the gas itself as the source of sulphuric acid for making the sulphate. These processes are somewhat complicated.

One of the latest applications connecting the manufacture of coke with the other arts is the "gas oven." This name has been applied to the by-product coke oven when adapted especially to the manufacture of illuminating gas. The essential modification is that the gas for heating the ovens is obtained from producers, the ovens being modified to suit this gas, so that the whole of the gas produced from the distillation of the coal in the oven is available for sale as illuminating gas. This adaptation of the retort oven is attracting considerable attention; several plants are in operation in Europe, and three or four are beginning operation or are in course of construction in the United States. While producing practically the same gas as other systems employed in coal-gas manufacture, the gas oven has the advantage of producing a high quality of coke. It also has the advantage in operating cost, due to the employment of larger units and carbonizing more coal per unit of labor. These plants are more especially adapted to the larger installations for gas manufacture.

In discussing the use of by-product coke for metallurgical purposes, the statement is often made that this coke cannot be as good as bee-hive coke, because the quality of the coke is injured in the manufacture in order to obtain better by-products. This is not the fact, as is borne out by the considerable number of by-product oven plants now supplying metallurgical coke for furnace and foundry work. In fact, in a number of localities by-product coke is sold for foundry purposes at a premium over the best bee-hive coke on the market.

One point in which by-product oven operation has improved in recent years is in reliability. In considering the gas, for example, either for gas-engine work or for illuminating purposes, reliability of supply is an absolute essential; and while formerly the supply of gas was uncertain and undependable, contracts are now made which insure a permanent and reliable

[1] Bulletin No. [illegible] of the University of Illinois (1909).

supply that can be depended upon, like any other manufactured product. The sales of oven gas for illuminating purposes now exceed 40,000,000 ft. per day.

The manufacture of by-product coke is coming to be not only an operation for the manufacture of coke and the saving of such incidental products as may be obtained, but rather an industry where coal is distilled for the purpose of producing several products, such as coke, tar, ammonia, benzol, gas, and perhaps others, each made of the best quality, and each important in maintaining the earnings of the plant. The growth of chemical manufactures in America and the greater demand for the products which supply these industries add permanency and reliability to the market, and at the same time the by-product oven furnishes a reliable supply of raw materials to important industries, which, although in some cases still in embryo here, have attained great proportions in Europe, and doubtless will grow to large importance in this country.

Mr. Andrews' Paper on By-Product Coke.

The paper by Mr. **Charles W. Andrews**, of Duluth, Minn., on "By-Product Coke," was presented in the absence of the author by Dr. Schniewind. He first gives a breif sketch of the developments of the by-product coke industry in the United States since 1893.

The New England Coke & Gas Company started the plant in Boston in 1899 which was destined to change the whole trend of the establishment of by-product plants, since it manufactured for the first time illuminating gas suitable for sale without enrichment. This was accomplished by dividing the gas on the battery into two portions. One portion consisting of the richer part of the gas was saved for sale, while the remaining, or leaner, portion was used in the battery.

This idea was originated by Dr. Schniewind, of the United Coke & Gas Company. The coke was used for domestic, industrial and locomotive fuel, as its sulphur content was too high to make it suitable for use in the foundry. The successful operation of this plant led to the building of additional plants at points where the production of illuminating gas could be sold to advantage and where there was a fair market for the coke output.

The author gives a list of illuminating-gas plants showing the rapid growth of this method of combined gas in coke manufacture, and also a list of by-product coke plants at iron and steel centers. The latter list shows that with comparatively few exceptions all the steel plants and blast furnaces lying outside of the coking-coal district receive almost their whole coke supply from the by-product ovens. This is a most decided change from fifteen years ago when Cambria was practically alone in the field.

The question is often asked why by-product ovens are not being built more freely in the central coking districts. To answer this question statistical figures are given showing the decline of the production of coke in bee-hive ovens and the increase of the production of coke in by-product ovens in recent years. As a very large proportion of the total bee-hive coke is produced in the central coking district, the present bee-hive ovens are ample to take care of the demand during ordinary years, consequently if the by-product plants were built by the present operators it would result in the loss of a large investment in bee-hive ovens necessary for a corresponding output. In addition the operators would practically be unable profitably to sell the gas for illuminating purposes owing to the competition of natural gas.

There is no doubt but that the gradual exhaustion of the coal and gas fields will eventually lead to the use of by-product ovens throughout the district, since the increase of practically 10 per cent in yield obtained by the by-product ovens, and a market for illuminating gas will eventually become of enough importance to justify the move.

As far back as 1898 the use of producer gas to heat the ovens either wholly or in part was suggested by Dr. Schniewind and an experimental installation was made at Boston for this purpose. Its use, however, was not extended owing to various reasons. Within the last two or three years, however, conditions at certain points have become more favorable for this form of gas production, and several systems have been devised whereby combination ovens are constructed. These ovens are so designed that either producer gas or lean oven gas can be used for heating the brickwork. In this way the ovens can be designed to take care of the summer consumption under most favorable conditions, and a producer-gas plant can take care of the increase in the winter consumption. This development will, no doubt, lead to the construction of a large number of comparatively small by-product plants throughout the United States. These plants would ordinarily make sufficient metallurgical coke to supply the needs of the local foundries and sell the remainder of the production for domestic use.

Apparently the final result of by-product oven construction will be the gradual spread of coke manufacture over practically the whole country instead of in the coking-coal districts.

Mr. Lucas' Paper on Coke.

A paper by Mr. **F. E. Lucas**, of Sydney, N. S., on the manufacture of coke was read, in the absence of the author, by Mr. Blauvelt. Coal is in a chemical respect coal with the volatile material distilled off, but it must also conform to certain specifications in respect to physical structure and the percentage of impurities present. The impurities in coke are principally sulphur and ash, of which the first gives the most trouble.

In this country we have had in the past available large quantities of coals which are naturally of a good coking quantity and require no preparatory treatment. The exhaustion of these coals is in sight, and it will in the future be necessary to put the coal through certain processes before charging in order to maintain the standard of coke.

If a coal is high in sulphur or ash it will have to be washed to remove as much as possible of these impurities. The mechanical devices employed for doing this are many and varied, but any one type of plant does not necessarily work to the best advantage on every coal. Each coal should be carefully studied and tested by all possible means before erecting any plant to prepare it for coking.

A further preparation which may become necessary will be the compression of the coal into cakes before charging. It is sometimes claimed that all coal should be stamped before charging, but the author does not agree with that claim. Compressing a coal which gives us under natural conditions such a coke as is desired, only closes in the cell structure and makes a heavier and denser coke. However, this does not alter the fact that in many cases compression of the charge is of incalculable benefit to the quality of the coke produced. Both washing and compression are almost universally practised in Europe.

The author then gives a sketch of the process of making coke and recovering by-products applicable to all kinds of by-product coke ovens. The part relating to by-products is here reproduced.

RECOVERY OF BY-PRODUCTS

The recovery of by-products in their first form takes place in the condensing plant. During the past few years there have been many new developments in recovery apparatus.

The older method of extracting tar and ammonia from the gas was to pass the gas through a series of coolers, bringing it down gradually to the vicinity of from 80 deg. F. to 90 deg. F., then pass it through the tar scrubbers, and then through the ammonia washers, where the gas was brought by various means into intimate contact with water. The water absorbed the ammonia, and this ammonia liquor was then distilled by steam, the ammonia vapor being driven off, and, in turn, absorbed in a bath of sulphuric acid, in which the ammonium sulphate was precipitated, and afterwards extracted and dried, ready for shipment.

The next process was a semi-direct one, in which the gas was cooled sufficiently to allow the tar to be extracted by the ordinary cooling method, and then the gas was heated up again and all passed through the sulphuric acid bath, which absorbed all the ammonia, while the gas passed on to the holder or oven. The sulphate in this case was precipitated and prepared for shipment as in the previous process.

In the semi-direct process a certain amount of weak ammoniacal liquor, consisting of the moisture which was condensed out of the gas in the original cooling, has to be dealt with in stills, the same as in the first process. The quantity of the liquor to be so dealt with will depend on the moisture in the coal charged into the ovens.

A third—the direct—process, consisting in taking the gas direct from the ovens without cooling, extracting the tar at this high temperature by specially designed apparatus, and then passing the whole of the gas through the acid bath, as in the previous process. By this method there is no liquor to be dealt with and there is also no lime needed in the process, as in the case where liquor has to be distilled and a certain amount of milk of lime has to be added to release the so-called fixed compounds of ammonia in the liquor.

There is still another process, as yet in the experimental stage, in which the gas is cooled and the tar extracted as in the process first described, but the ammonia is recovered in the form of sulphate by utilizing the hydrogen sulphide in the gas instead of sulphuric acid.

QUENCHING OF COKE

The quenching of the coke is important from both the standpoint of moisture content and of strength. If the coke gets too much water, the cells will suck themselves full as they cool and there will not be heat enough left to expel this excessive moisture. At the same time, the rapid formation of steam has a tendency to crack the coke and weaken it materially. The ideal quenching of coke can be shown by immersing a piece in water, just for a moment, immediately after it comes from the ovens, and then leaving it for about 20 minutes. The water has just chilled the outside and stopped any tendency to combustion there. The inside will die out for want of air, and at the same time there will be sufficient heat to dry out the moisture from the outer cells. It is probably not possible in actual practice to get such results as we would in a small experiment, but the nearer we approach to it, the better the product will be.

The effect of moisture in the coke is one on which opinions may differ. The buyer of the coke, of course, does not care to pay for the moisture contained or pay freight on it. But the effect of moisture in the coke on the action of the furnace or cupola itself is not so clear. In the foundry cupola, where the ratio of coke to iron melted is so low and the distance between the top and the melting zone so short, the question of moisture may be very important; but in the blast furnace we have a very different condition. The author does not see how a reasonable amount of moisture in the coke can affect the melting zone of the furnace or the reducing action of the gas on the ore. There is a temperature at the top of the furnace, where the coke is charged, high enough to thoroughly dry out the moisture before the coke gets far enough down to do any good, and the moisture is carried off with the gas. In fact, there are some furnace plants where the coke is sprayed with water before charging in order to keep the top heat down below the danger limit.

Then comes the question of the effect of the moisture on the gas itself. As long as the moisture is not high enough to limit the heats required to be raised on the stoves, the author cannot see that it has done any harm.

The author emphasizes that manufacture of coke in bee-hive ovens is probably the greatest waste this country has ever seen. The by-product oven gives besides the coke also surplus gas which may be used for gas engines or as an illuminating gas, further, ammonia and tar.

In the year 1911 there was produced in America approximately 29,338,000 tons of coke, of which approximately 21,448,000 tons was produced in bee-hive ovens. If these tons of coke had been produced in by-product ovens instead of bee-hive ovens the author figures that there would have been produced surplus gas of a value of $10,400,000, ammonium sulphate at a value of $10,446,000, and tar at a value of $3,640,000; the total value of ammonia and tar being $24,500,000.

The above amount is 7 per cent on about $350,000,000, a sum which would build by-product ovens enough to carbonize 125,000,000 tons of coal yearly. Besides this loss, there has been the loss of the coal burned in the bee-hive oven. Allowing 64 per cent as a fair yield for the bee-hive and 78 per cent for the by-product ovens, there would be a loss exceeding 6,000,000 tons of coal. This at $1 per ton added to the other loss gives us a grand total of over $30,000,000 lost in one year. It seems that this is well worth "getting after." The author finally gives a detailed comparison between bee-hive and by-product ovens and figures that for a plant of 100 by-product ovens with an oven charge of 9 tons the yearly saving would be $455,155. The cost of the 100-oven plant complete is approximately $1,000,000. A 100-oven plant of above capacity will produce 630 tons of coke per day = 229,950 tons per year, working on 24-hour coking time. If benzol is recovered it will further add to the income from by-products.

Discussion on Coke.

The three papers were taken up together and elicited an extended and spirited discussion in which Messrs. James E. Thropp, Jr., James F. Kemp, E. V. d'Invilliers, F. Schniewind, R. Moldenke (in a communicated discussion), Bradley Stoughton, H. H. Stock, Charles H. Fulton, Ralph H. Sweetser, and W. H. Blauvelt participated.

In reply to the question as to what the maximum percentage of oxygen is which is permitted in coking coals Mr. Blauvelt said that this varied, but an oxygen containing 8 or 9 per cent would probably be considered high. Dr. Schniewind said that the oxygen alone was not the deciding factor; it is the relation of oxygen to nitrogen, the combination being in the ratio of 8 to 1. With respect to the swelling of coke, Mr. Blauvelt said that many low volatile coals swell considerably, but that the tendency of swelling could be counteracted by mixing such coal with other coal.

Dr. Schniewind discussed at considerable length the question of vertical versus horizontal flues and some essential details of operation in Otto-Hoffman versus Semet-Solvay practice. He thought that the general and logical practice of circulating gases was in a vertical direction. In his practice he found it necessary to provide for a slow travel of the gases and an absolute exclusion of external gases. He thought that Mr. Blauvelt's reference to boiler practice was not conclusive since the heating conditions in a boiler and in a coke oven are very different. Dr. Schniewind emphasized his opinion that in the boiler we have to do with transfer of heat by convection and in the coke oven with transfer of heat by radiation. The temperature difference is very different in both cases. When heat is transferred by convection it is necessary to provide for rapid movement in order to remove the adhering film from the flues, but it is not so in coke ovens, where radiation of heat counts and where it is found in practice that a slow movement of the gases improves the operating conditions. He also thought that the partition walls in the Solvay ovens were detrimental.

Mr. Blauvelt, in his reply, doubted the correctness of Dr. Schniewind's distinction between heat transfer by convection and radiation in case of boilers and coke ovens respectively. (Professor Fulton suggested later that what Dr. Schniewind meant was not a convection, but a conduction of heat.) As to the middle walls in the Semet-Solvay ovens he agreed that they take some space, but besides the other advantages stated in his paper above he emphasized that they were very useful as a reservoir of heat which comes very handy when a fresh charge of coal is introduced.

Mr. E. W. Parker, of the Geological Survey, said that last year the value of by-products obtained from by-product coke ovens was equal to the value of the coal charged into the ovens. Mr. Blauvelt warned the hearers not to take this statement as meaning that the coke didn't cost anything.

Mr. Bradley Stoughton referred to the successful use of tar in open-hearth furnaces as fuel by one steel company in this country. When more by-product coke ovens are erected there will hardly be much trouble in finding a market for by-products.

* * *

The Concentration of Iron Ores.

A paper on the concentration of iron ores was presented by Mr. **N. V. Hansell,** of New York. The importance of the concentration of low-grade iron ores lies not only in the fact that it makes possible the use of ores heretofore discarded, but also in the production of a raw material for the blast furnace that is physically more uniform and chemically purer, and may therefore command a higher price in future.

The various methods at present commercially used in the concentration of iron ores can be classified as follows:

1. Washing of brown, clayey ores and sandy hematite usually without previous crushing.
2. Wet separation on jigs and tables of hard hematites, after crushing and sizing.
3. Dry separating processes of hematites.
4. Magnetic separation of magnetites (and in a few cases mixed magnetites and hematites) either dry or wet.

The choice of a method depends almost entirely on the character of the crude ore. It is first necessary to carefully investigate the ore in the field and in the laboratory (where much useful information may be derived from microphotographic methods) and this is to be followed by crushing and concentrating tests in the testing plant.

The next chapters of the paper summarize recent progress in crushing, washing, jigging, dry concentration and magnetic saturation. Since these chapters are already in the form of greatly condensed information it is impossible to abstract them further.

In conclusion the author makes the following remarks:

In making the first rough estimates on the probable revenue in the exploitation of a low-grade concentrating iron-ore, proper attention must necessarily be given to the tonnage of ore available and to the cost of mining it. Generally, any low-grade proposition requires the investment of a large capital in a concentrating plant and in many cases in an agglomeration plant, indispensable for the conversion of the fine concentrate into a marketable product. The operations have therefore to be laid out in a large scale because otherwise the fixed charges distributed on the tonnage will make the cost of production seem prohibitive. A large tonnage of ore in sight, insuring operations in large scale for a number of years, is therefore a prerequisite.

In the case of iron ore, it is generally not difficult to predetermine the available supply of ore, and with magnetic ores it is even easier than with hematites, because the magnetic qualities of the ore make it convenient to employ some method of magneto-metrically surveying the ore deposit. If correctly done, this will give the extent in field of the ore deposit together with useful data on the dip and pitch. By a few diamond-drill holes, where the magneto-metric map indicates the best location for them, the quality of the ore in depth and its continuity are determined.

With these preliminaries well done, the development of the deposit can be quite accurately planned. The cost of the various operations can be estimated very closely from figures obtained elsewhere in similar undertakings, and modified to suit the local conditions as experience dictates. The usual risk generally considered inherent to mining enterprises is almost entirely absent. The consumption of iron ores is large and as a rule increasing from year to year. The American production of pig iron during the last 100 years has on the average somewhat more than doubled in each decade. The market is therefore well established. The market price of the ore has varied considerably and has, the last couple of years, been very low. It is, however, at present improving. In the light of the rapidly growing consumption it is not assuming too much to believe that it will never reach a lower point than it has in the past season. The easily available ores of good quality are, as is well known, very limited in extent and are controlled by companies not desirous of exhausting them at too rapid a rate. The foreign ores of high grade are available chiefly on the coasts. Their transportation far inland would make their cost prohibitive.

By taking all these conditions into consideration, one can feel reasonably certain in calculations of the probable revenue in the development of a low-grade iron ore proposition, using the present ore prices at the various furnace districts as a basis in finding the value of the concentrated and agglomerated product.

It is interesting to compare the various items of cost entering into the production of a high-grade blast-furnace material from a low-grade magnetic ore. We may take as an example an ore averaging 36 per cent. of iron in its crude state and occurring in such a large deposit that for several years to come it can be mined in open quarry and loaded with the steam shovel. If the intention is to produce concentrate with 64 per cent. of iron, it will be necessary to mine two tons of crude ore to make one ton of finished product.

The plant is, we will say, laid out for the treatment of 2000 tons of crude ore daily, which corresponds to 1000 tons of concentrate in 24 hours. A plant of this tonnage can be considered of normal size. It is assumed that power can be obtained in the form of water power and that transmitted to the works it does not cost more than $25 per horsepower year.

Labor is calculated at 20 cents per hour. The quarry and coarse-crushing plant are operated only in the day time because labor enters heavily especially into the quarry operations, and therefore better economy is obtained by accumulating during the day-shift enough crushed ore, which is distributed in the bins over the fine-crushing plant, to last over night. The quarry and coarse-crushing machinery is also easily obtainable in large units making it convenient and econominal to handle from 200 to 300 tons per hour.

In such a plant the following items of cost would enter into the cost of producing one ton of finished product:

Mining and transportation to crusher	$0.75
Crushing	0.10
Grinding and concentration	0.40
Agglomeration	0.50
Tailing handling and pumps	0.05
Shops, local administration, taxes, insurance	0.15
	$1.05

To this cost of manufacture is to be added the royalty on the ore as mined or as shipped, charges on account of the sinking fund, selling expenses and freight to furnaces. These will probably bring the total estimate for the agglomerated product laid down at the furnace to $3.75 per ton.

As soon as the operations have reached the point where it is necessary to resort to underground mining, the cost of the product will be increased, but the calculations still show a profit in the operations on account of the high quality of the material with its freedom from phosphorus and sulphur, which will make it bring a premium on the market.

The paper was briefly discussed by Messrs. Spilsbury, Moore, Johnson and d'Invilliers, and the question was brought up why expensive processes are now being used on medium-grade ores when the old log-washing process was formerly used on much lower grade ores with success.

Iron Blast Furnace Slags.

Mr. **J. E. Johnson, Jr.**, of Ashland, Wis., then presented his paper on "The Effect of Alumina in Blast Furnace Slags." The author emphasized that most of the work done in the past by scientists on blast furnace slags is of little value for practical purposes since the important point of a given slag is neither its total heat of fusion nor its softening temperature, but its free-running temperature, since this is the critical temperature of the furnace. This temperature bears no definite relation to the softening temperature.

As to slag calculations, any college student can learn in a day how to make them, if there are given to him the materials to be used and the slag to be produced. But, first, the slag to be produced must be known and it is known only by experiment and experience with the furnace itself.

The object to be sought is as follows: Given the materials to be used and the kind of iron to be made, to ascertain the slag which will produce the result with the least cost for coke and for flux, and will permit the greatest out-put. The three desiderata come in the order given.

Since generally the lowest fuel consumption is obtained with the lowest critical temperature, the object desired may be stated more definitely as the production of the most fusible slag that will give the necessary desulphurization of the iron. This statement is perhaps subject to certain limitations from the fact that there are circumstances in which it is necessary to raise the critical temperature in order to enable the iron to absorb a large quantity of silicon.

While the effect of lime is to increase the basicity of slag and facilitate the removal of sulphur, its use is subject to grave limitations, for two reasons: First, the lime being generally the major ingredient of the slag, to increase the percentage of the lime in the slag involves a more than proportional increase in the slag volume.

Second, (and much more important), the addition of lime raises the fusion point of the slag very rapidly.

The desulphurizing effect of the slag is proportional, not only to its basicity, but also to its fluidity in an almost equal degree, so that while increased lime *per se* has a desulphurizing influence, this is, to an increasing extent, neutralized and finally reversed completely by its decreased physical activity.

This is well shown in basic practice, in which the highest sulphur iron is made, not with deficient lime, but with an excess (due to a change in ore or the like) so great that the heat available is unable to bring the very refractory slag to the free-running condition.

In further illustration of the point, there are two distinct methods of making this kind of iron. The first consists in running on a very calcareous slag, with which the silicon in the iron is kept down by the basicity of the slag in spite of the high temperature necessary to keep the latter fluid. The second consists in maintaining a slag of only moderate basicity and much lower fusion temperature and keeping down the silicon by carrying a heavy ore burden, which, of course, can easily be done with the lower critical temperature.

Furnaces running on the first plan always require more coke for basic than for foundry iron, while those running on the second plan use less than for foundry iron.

It seems practically certain, therefore, that there is a considerable range of lime content in the slag for given conditions, in which the desulphurization of the iron is not appreciably affected, while the coke consumption necessarily rises with the increase in the fusion temperature consequent on the high lime ratio, as well as the increased slag volume.

Mr. Johnson then takes up the effect of magnesia and points out in all theoretical slag calculations the quantity of magnesia is multiplied by 1.4 to put it on the same basis as the lime, which, from the point of view of the oxygen ratio and molecular weights, is perfectly correct. Practically, however, this does not work out.

The truth seems to be that magnesia is less active chemically than lime in about the same proportion that its molecular weight is less.

It is very necessary, however, to recognize that the addition of a certain amount of magnesia has a marked effect in lowering the fusion temperature of the slag and is therefore of great use where calcareous slags are required, particularly in the manufacture of basic iron.

For practical purposes lime and magnesia may be considered as being of equal value.

The author then takes up the main subject of his paper, which is the effect of alumina in blast furnace slags.

The effect of alumina has been the subject of much discussion; some regard it as an acid, others as a base, while a few declare it can be made to act as a base or an acid almost at will.

It has seemed to Mr. Johnson that under such circumstances the probability was that its action was neither acid or basic, but was perfectly neutral, simply a diluent affecting the viscosity of the slag to some extent, but, with a given ratio of lime to silica, not affecting its chemical nature at all. The author produced considerable evidence from practice to support the correctness of this view.

The subject was discussed at some length, in spite of the lateness of the hour. Mr. Sweetser said that the paper had opened one of the most useful discussions for blast furnace men, and paid a high compliment to Mr. Johnson's paper, although he did not agree with his views on the effect of alumina.

Prof. Fulton emphasized that the slag composition should be looked upon from the standpoint of physical chemistry. The entities constituting a slag are certain minerals. Most slags consist of two minerals only, which fact simplifies the theory very essentially. On this basis the action of alumina may be simply explained. After some remarks by Prof. Kemp on the fusion point of minerals, the meeting adjourned.

Business Session.

The whole morning of Wednesday was devoted to a business session which was held again in the Assembly Room of the Hotel Statler. In behalf of a special committee consisting of Dr. Jos. W. Richards, chairman, and Messrs. Charles Kirchhoff and Charles F. Rand, Mr. Rand presented the new proposed constitution for the Institute as worked out by the committee after most painstaking deliberation.

Two special points came in for an extended and animated discussion. The first was a proposition to provide what would be in fact a new and superior class of members, called the "Fellows" of the Institute, and to give them the right to express their opinion with regard to pending or proposed legislation affecting the mining and metallurgical industries.

There were many speeches made both for and against the proposition. For the proposition it was argued that in the past the Institute had been too indiscriminate in electing members and that a class should be made of those members who have the higher qualifications of a mining engineer. Further that it would be advisable that if not the whole Institute, at least somebody within the Institute, should have the right to express an opinion of pending problems of national importance.

Against the proposition it was pointed out that the class of Fellows would represent an organization within the organization. It would be a self-perpetuating body. It would be a dangerous departure from the ideals of the American Institute of Mining Engineers which, as Mr. Johnson said, has always been "the great democratic engineering society." As to the advisability of expressing an opinion on pending problems Mr. Johnson asked: If sixteen years ago the Institute had expressed an opinion on the free silver question in which its members were certainly interested, what would have become of the Institute? Further, the question was asked,

Would it be advisable now for the Institute to express an opinion on the tariff in which the members are certainly interested?

The outcome of the discussion was that it was voted to be the sense of the meeting that the paragraph in the proposed constitution giving the Fellows the right to express an opinion should be stricken out (the vote being 33 to 17). Further, it was voted to be the sense of the meeting that the class of Fellows should not be created (the vote being 27 against the Fellows and 20 in favor).

The second point which came up for extended discussion referred to the question whether the Secretary of the Institute should be restricted to devote his whole time to the Institute. The vote was 30 against this restriction and 13 in favor of it.

Of course, as the proposed constitution will be submitted to all the members for a vote, the vote taken was simply for the purpose of ascertaining the opinion of those who attended the Cleveland meeting and listened to the long and detailed discussion.

The concluding session was held on Friday morning in the Case School of Applied Science, in the large lecture room of the Department of Physics.

* * *

Charcoal Iron.

The first paper was presented by Mr. **J. E. Johnson, Jr.**, on "the effect of carbon on the quality of charcoal iron" which elicited considerable interest and was discussed by Mr. Bradley Stoughton and in a communicated discussion by Prof. Howe. Mr. Stoughton paid a high tribute to the results which Mr. Johnson has already obtained in his scientific research and which he had been able to turn into a commercial or practical success.

Mr. Johnson's paper was illustrated by numerous interesting lantern slides. In view of the importance of the paper it is printed in full elsewhere in this issue.

* * *

The Series of Copper Slags.

Prof. **Chas. H. Fulton,** of Cleveland, O., in his paper on this subject, pointed out that the classic work of J. H. L. Vogt, who views slags from the standpoint of physical mixtures (solutions in which the entities are minerals), has opened up a new field in the study of slags, and has placed the investigation of such properties as melting temperatures, etc., on a rational basis. The author's own work recorded in the present paper is the result of an investigation of reverberatory furnace slags made for a Western smelting company to determine exactly the influence of change in composition, within comparatively narrow limits, on the melting point.

In view of the fundamental importance of Prof. Fulton's paper it will be printed practically in full in one of our next issues. We give here only a brief summary. After an introduction on the mineral series of copper and lead slags, the author deals with the constitution of certain reverberatory slags and then takes up the melting point of slags giving curves both for the melting point and for the fluidity or free-running temperature. The latter is, of course, the temperature which is of practical importance. The two curves are by no means always parallel and the variation between the two temperatures is quite interesting.

The slags of lower melting point lie roughly between a silicate degree of 1.4 and 1.65, dependent upon the base composition. This confirms what has long been the opinion of copper metallurgists. With a given silicate degree, within the range of 1.70 to 1.00, the replacement of iron and lime by some alumina, up to 11 per cent, lowers the melting point. In a given slag of certain silicate degree within the range specified, the replacement of iron by lime raises the melting point somewhat. This, however, does not mean that a pure ferrous bisilicate, for instance, has a lower melting point than one in which some iron is replaced by lime, for this condition would be expressed by the series hypersthene-augite, in which a eutectic may also occur. It has reference to series of minerals in each of which lime is necessarily present, as sugite-elilite. Then of two slags, each of the same silicate degree, the one with relatively more lime has the higher melting point. The slags investigated have melting points that lie between 970 deg. and 1220 deg. C. The slags of higher silicate degree have comparatively low melting points.

When, however, the fluidity curves are examined in connection with the melting point curves it is seen that the gap between the two curves widens rapidly as the silicate degree increases, and while from 25 deg. to 40 deg. of superheating is sufficient in the vicinity of the ortho-silicate, from 150 deg. to 175 deg. is required to superheat to fluidity at a silicate degree of 1.5. Increased alumina accentuates the gap greatly, and the more highly aluminous slags, due to their great viscosity, require much superheating above the melting point in order to obtain enough fluidity. It is this phenomenon which makes high silica, high alumina slags so difficult to work. The minerals orthoclase and albite, high in alumina and silica, are extremely viscous.

Slags approaching near the bisilicate are looked upon with suspicion for reverberatory furnace work particularly. Of late, however, the incentive to make the more highly siliceous slags has been great. On the score of formation temperature and melting point nothing can be urged against these slags, but they do require much superheating, especially if alumina rises above 5 or 6 per cent. There seems to be no good reason why they could not be made in furnaces of ample temperature reserve, such as the present oil-fired furnaces.

* * *

Metallurgy of Copper.

Two further papers relating to the metallurgy of copper were then presented.

Mr. **Frederick Laist,** of Anaconda, Mont., read his paper on the chemistry of the reduction processes in use in Anaconda. This paper was already presented before the International Congress of Applied Chemistry and was printed in our issue of September 12 page 592.

A paper by Mr. **E. P. Mathewson,** of Anaconda, Mont., on the development of the reverberatory furnace for melting copper ores was read by title. It had also been presented before the International Congress of Applied Chemistry, and was printed in our issue of September 12, page 591.

* * *

National Resources and the Federal Government.

A paper by Dr. **R. W. Raymond** on "our national resources and our Federal Government" was read by title, and Dr. W. E. Parker presented a paper by Dr. **George Otis Smith,** head of the Geological Survey, in which he took the issue with some of Dr. Raymond's statements and opinions.

* * *

Case Hardening of Special Steels.

A paper by Dr. **Albert Sauveur** and Mr. **G. A. Reinhardt,** of Harvard University, entitled "Note on the Case Hardening of Special Steels," was presented by Mr. Reinhardt. The authors point out that although many metallurgists know that some pearlitic special steels can be made troostitic, martensitic, and even austenitic, without quenching, and, therefore, without exposing them to the dangers of the quenching bath, the practical significance of such possibility does not seem to have received the attention it deserves.

With reference to the constitutional diagram of nickel iron carbon steels it is pointed out that theoretically starting with pearlitic steel, then by increasing the carbon content or the nickel content, or both, the metal should become martensitic

and eventually austenite. In this way there should be a possibility of imparting to the metal, without quenching it, the properties of hardened carbon steel. In other words, the steel is now self-hardening. Nickel cannot be introduced into solid steel, but by the well-known process of case hardening it should be possible to cause pearlitic nickel steel to absorb the necessary amount of carbon to become martensitic, or, even, if desired, austenitic.

It should, therefore, be possible to manufacture case-hardened objects of nickel steel and of some other special steels having pearlitic and consequently soft and tough cores and troosto-martensitic, martensitic, martenso-austenitic or austenitic cases, without recourse to the quenching bath. The authors give the results of some experiments showing the practicability of the manufacture of case hardened articles of this description. For instance, steel containing some 3.5 per cent of nickel can be made martensitic by case hardening followed by air cooling. Slow cooling in the furnace produces a sorbito-cementitic case.

Further, in case-hardening nickel-steel containing about 5 per cent of nickel, austenitic or martensitic cases can readily be produced through proper regulation of the length of the operation and by cooling in air the case-hardened articles. Slow cooling in the furnace produces sorbito-cementitic cases.

By reheating to 1000 deg. C. a steel with a sorbito-cementitic case (because of slow cooling in the furnace) and cooling in air, the case became martensitic. This suggests the advisability of cooling in the furnace after case-hardening, producing a corbito-cementitic case and then reheating to 800 deg. C. and cooling in air, thereby securing a finer martensitic case than by cooling in air from the case-hardening temperature.

Mr. C. R. Corning presented a few additional remarks on the proposed changes of the constitution and by-laws and the meeting then adjourned with a hearty vote of thanks to the local committee and all who made the meeting so successful and enjoyable. Many members then enjoyed the opportunity of inspecting the different buildings of the Case School of Applied Science.

* * *

Excursions and Social Functions.

On the evening of Tuesday the members and guests of the Institute were entertained at an informal smoker at the Statler Hotel. There were many ladies present. The motion picture series "From Mine to Molder" was shown by courtesy of Messrs. Rogers, Brown & Company, with an accompanying explanation of Mr. Henry B. B. Yergason, of the staff of that company. Prof. James F. Kemp then made a very entertaining address, showing some of his remarkable mountain climbing photographs.

On Wednesday evening a well attended banquet was held at the Hotel Statler, with Mr. D. T. Croxton as a brilliant toastmaster. Addresses were made by Captain Hunt, Mr. William J. Mather, Mr. Philip N. Moore, Mr. Edward W. Parker, Mr. Edward H. Benjamin, Mr. William Kelly, Mr. Samuel T. Wellmann, Prof. James F. Kemp and Mr. Charles Kirchhoff. Telegrams of greeting were sent to "Uncle" John Fritz and Dr. R. W. Raymond.

Mr. Kirchhoff in his after-dinner speech offered another amendment of the proposed constitution to catch up with the spirit of the times. He proposed that in future in similar functions of the Institute the wife, daughter, friend or present or future sweetheart should follow each mere man speaker, but that the conservatism of the Institute should be maintained by reserving the last word for mere man.

The afternoons of Wednesday and Thursday were devoted to very interesting excursions. On Wednesday afternoon the American Steel & Wire Company was visited. On Thursday afternoon the plant of the National Carbon Company and the ore docks of Mr. M. A. Hanna & Co.

At the works of the National Carbon Company the party was taken through the well-equipped library, the arc-lamp testing laboratory and the dry-cell testing room. The manufacture of dry cells was shown through its various stages as well as the mixing and grinding rooms for the arc-lamp electrodes, brushes and cells. The process of forcing arc-lamp carbons through dies and the molding of carbon brushes and dry-cell electrodes under hydraulic pressure were shown. The furnace room was visited in which the carbon products are baked. The party finally visited the brush-testing laboratory where tests are made of the specific resistance, strength, hardness, density, as well as friction tests at various speeds and contact-resistance tests at different brush pressures and current densities.

The whole visit was exceedingly enjoyable and the visitors were placed under great obligations to Mr. J. S. Crider, general manager, and Mr. H. A. Barren, general superintendent, of the National Carbon Company, as well as to the various members of the staff of the company who showed the visitors around.

For the visiting ladies an automobile ride through Cleveland's boulevards was given on Tuesday afternoon, followed by a tea at the Country Club.

In the following we give a complete alphabetical list of all members and guests who registered at the meeting. When no city is stated, Cleveland is meant:

Robert Abbett, Mark A. Aborn; J. S. Appleyard, Youngstown, Ohio; A. Arluck, A. O. Backert, A. C. Badger; H. Foster Bain, San Francisco, Cal.; H. A. Barren; W. H. Barrows, Jr., Duluth, Minn.; Edward H. Benjamin, San Francisco, Cal.; C. A. Bever; W. H. Blauvelt, Syracuse, N. Y., R. T. Boynton, New York; Arthur J. Boyle, New York City; H. T. Braman, Youngstown, Ohio; M. S. Brayer, Sharon, Pa.; J. H. Byrne; L. W. Callender, C. S. Carey; H. O. Chute, New York; Thos. H. Clagett, Bluefield, W. Va.; W. W. Coe, Roanoke, Va.; L. A. Collier; Geo. L. Collord, Sharon, Pa.; Edgar I. Cook, Pottstown, Pa.; C. R. Corning, New York; Jenning S. Cox, Jr., Santiago de Cuba; W. N. Crafts, Benedict Crowell, Mr. and Mrs. D. T. Croxton, S. W. Croxton, H. D. Dalton, A. E. Danforth; E. V. D'Envilliers, Philadelphia, Pa.; Mr. and Mrs. L. E. Dunham, Mr. and Mrs. F. A. Emmerton; W. E. C. Eustis, Boston, Mass.; Augustus H. Eustus, Boston, Mass.; A. I. Findley, New York City; E. L. Ford, D. D. Fowler, P. A. Fruehauf, Charles H. Fulton, H. F. Fulton; James Gayley, New York City; Stephen L. Goodale, Pittsburgh, Pa.; A. L. Gresham, New York; C. L. Griswold, Pittsburgh, Pa.; H. C. Hale; J. H. Hamilton, New York City; N. V. Hansell, New York City; H. T. Harrison; Elwood Haynes, Kokomo, Ind.; R. P. Heston, Toledo, Ohio; Henry D. Hibbard, Plainfield, N. J.; Henry H. Hindshaw, Alpena, Mich; W. H. Hoyt; Mr. and Mrs. Geo. S. Humphrey, New York City; Robert W. Hunt, Chicago, Ill.; J. D. Ireland, Duluth, Minn.; L. E. Ives; F. G. Jewitt, Minneapolis, Minn.; Mr. and Mrs. J. E. Johnson, Jr., Ashland, Wis.; Nason Johnson, Alpena, Mich.; Mr. and Mrs. William Kelly, Vulcan, Mich.; J. F. Kemp, New York City; Paul H. King, Philadelphia, Pa.; Mr. and Mrs. Charles Kirchhoff; G. F. Knapp, Wm. Koehler; H. M. LaFollette, LaFollette, Tenn.; Frederick Laist, Anaconda, Mont.; E. F. Lake, Horace W. Lash; A. R. Ledoux, New York City; I. P. Lihme, J. B. Livingston; E. J. Longyear, Minneapolis, Minn.; D. A. Lyon, Pittsburgh, Pa.; A. G. McKee; W. W. Macon, Brooklyn, N. Y.; J. W. Malcolmson, Kansas City, Mo.; S. W. Marshall, Johnston, Pa.; H. A. Marting, Ironton, Ohio; Samuel Mather, W. G. Mather; Paul O. Menke, Sharon, Pa.; H. G. Merry, L. B. Miller; Philip N. Moore, St. Louis, Mo.; W. D. B. Motter, Jr., Trenton, Ont., Can.; Mr. and Mrs. C. B. Murray; Edward W. Parker, Washington, D. C.; H. P. Parrock, Buffalo, N. Y.; Wm. Pecanka; J. S. Pelton, New York City; Geo. W. Pfeiffer, Santiago de Cuba; C. B. Pierce; Mr. and Mrs. S. H. Pitkin, Akron, Ohio; Franklin Playter, Boston, Mass.; J. D. Price, New Straitesville, Ohio; John M. Price; Mr. and Mrs. Charles F. Rand, New York City; W. B. Ranney, Lakewood, Ohio; William Rattle, Jr., J. B. Read; G. A. Reinhardt, Cambridge, Mass.; J. C. Reitz, West Park, Ohio; F. B. Richard; C. Snelling Robinson, Youngstown, Ohio; E. F. Roeber, New York City; Willard N. Sawyer, C. A. Schaefer; F. Schniewind, Englewood, N. J.; Dr. W. Schumacher, Berlin, Germany; R. B. Sheridan; J. M. Sherrerd, Easton, Pa.; Albert W. Smith; E. Gybbon Spilsbury, New York City; S. C. Stillwagon, T. D. Stay, H. S. Stebbins; H. H. Stoek, Urbana, Ill.; Mr. and Mrs. Bradley Stoughton, New York City; Jos. Struthers, New York City; Mr. and Mrs. R. H. Sweetser, Columbus, Ohio; Mr. and Mrs. Knox Taylor, High Bridge, N. J.; R. B. Textor, Oscar Textor; Mr. and Mrs. J. Earlson Thropp, Jr., Indiana Harbor, Ind.; F. H. Treat; B. W. Vallat, Ironwood, Mich.; Frank R. Van Horn; Felix A. Vogel, New York; Karl E. Volk, West Park, Ohio; Fred F. Walther; C. M. Weld, Low Moor, Va.; S. T. Wellman, Edmund Wendel, M. T. Whelan, C. L. Wood; Walter Wood, Philadelphia, Pa.; Henry R. B. Yergason, Cincinnati, Ohio; G. A. Yoeum; Carl Zapffe, Brainerd, Minn.; Jeffries Zay.

River Water Used Eight Times.—Power can be developed upon many surface streams and applied to the recovery of the water of the streams after it has sunk into the earth in the lower lands of the valleys. An instance of this character according to the United States Geological Survey is to be found along Santa Ana River in southern California. After storing in a reservoir, it is used in succession in various power plants, for irrigation purposes, and for municipal water supply. In this particular case the same water is used in succession eight times for power and irrigation. (Water Supply Paper, 234, Geological Survey.)

Synopsis of Recent Chemical and Metallurgical Literature.

Gold and Silver.

Collection of Precious Metals as Speiss.—The way in which a supposed disadvantage was turned to good account is recorded by Mr. G. C. McMURTRY, in *Bulletin* No. 97, Institution of Mining and Metallurgy. The object of a certain smelting operation was to produce a low-grade copper matte high in gold. At odd times it was noticed that a small amount of speiss was formed in the smelting, and when this happened the value of the matte in gold decreased. The author believed that if this formation of matte could be controlled, it would form a good means of recovering the bulk of the precious metal. Experiments were therefore undertaken which resulted successfully.

The materials smelted consisted of raw concentrates, roasted concentrates and slimes from a previous method of treatment, copper ore and limestone flux. The roasted materials formed the largest portion of the smelting charge, but before smelting they were mixed with the raw concentrates and re-roasted.

The raw concentrates 13 to 33 per cent SiO_2, 29 per cent Fe, 26 to 30 per cent S, 14 to 20 per cent As, 1.5 to 3.5 per cent Sb, and 3 to 5 oz. Au per ton. The roasted concentrates and slimes had been roasted practically free from sulphur and arsenic, but contained about the same antimony as the raw concentrates. The copper was a pyrite containing about 8 per cent copper.

A bath of matte was formed, on which was charged the hot auriferous material from the roaster with some raw copper ore and limestone. Charging was continued until the matte assayed from 40 to 60 oz. per ton gold.

With a reverberatory furnace of good bottom the formation of speiss could be effected better in the furnace, but this was impossible on account of the poor condition of the furnace at the author's disposal. Consequently the matte was tapped into sand beds where it flowed over scrap wrought iron, with the resulting precipitation of antimonial speiss carrying a fair proportion of gold. The lower the percentage of copper in the matte, the better the gold recovery in the speiss. With mattes above 32 per cent copper the recovery was very small.

The speiss thus formed was separated from the matte, the latter being returned to the furnace to receive a new charge of roasted material, copper ore and limestone. The speiss was remelted in plumbago pots, and granulated by pouring into water.

The next operation was to give the speiss a sinter-roast in a conical pot holding about 40 lb. A false perforated bottom was placed in the pot, which was adapted to receive an air-blast. The granulated speiss was mixed with half its weight of siliceous arsenical concentrate, a small handful of fine coal being added to each 21 lb. of mixture. A light fire was started on the false bottom of the pot, after which the mixture was fed gradually and a light blast turned on. Ultimately the pot was filled and roasted for about 1½ hours. The object of the roast was to render the iron and copper amenable to the treatment in the next step of the process.

This consisted in remelting the sintered speiss with copper ore, cyanide slag and sand. The copper was added in lieu of iron pyrite. The result of the operation gave an enriched speiss and a matte with some slag. The last was skimmed and the balance poured into molds and separated when cold.

The gold was finally recovered by cupelling the speiss with lead. The author realizes that the different steps of the process are not perfect, but they were adapted to conditions in an isolated position.

Magnetically-Removed Iron from Mill Pulp.—In a paper published by A. McA. JOHNSTON in the August, 1912 *Journal* of the Chem. Met. & Min. Soc. of S. Africa, the author gives the results of an investigation of the presence and effect of metallic iron in the pulp circulating in cyanide mills. The following summary of his results is given.

1.—Iron is obtained chiefly from the crushing plant, and is mostly present as small pieces, smaller than a pea, or as fine powder. It tends to accumulate in the tube-mill circuit.

2.—Iron in this state interferes with amalgamation and with regrinding in the tube-mill, while it consumes cyanide in the leaching vats.

3.—When removed from the pulp, this product can be easily oxidized by exposure to the atmosphere, wetting and turning over frequently.

4.—Failing any better means of disposal, this oxidized product will, if fed into the circuit, yield an average percentage of its gold to amalgamation and cyaniding.

Copper.

Flotation of Ore.—The application of the minerals separation flotation process on a copper ore in New South Wales is described in *Bulletin* No. 97, by J. W. ASHCROFT. The former treatment of the ore was by concentration on jigs and tables, and it was the tailings and middlings from this process that were treated by flotation.

The author describes at some length his experience in finally adopting the process to his ore and gives the following conditions for successful working.

1.—The particles must be clean and free from oxidation.

2.—The gangue must not be so clayey as to form a coating on the sulphide particles.

3.—The material treated requires to be ground as evenly as possible; the best size must be determined for each ore.

4.—The feed to the separating machine and the speed of the stirrers must be correctly proportioned and kept as even as possible.

5.—The thickness of the pulp fed to the machine must be regulated and kept even.

6.—The minimum amount of mineral present in the feed must be determined.

7.—The water used has a marked effect on the process and necessitates modification according to its hardness and chemical constituents, but a bad water is not necessarily detrimental.

Assaying.

Preparation of Samples.—Mr. W. B. BLYTH calls attention to the necessity of proper preparation of mine samples, if the resulting assay is to be of value. His paper appears in the July, 1912, *Journal* of the Chamber of Mines of Western Australia. The main point to be observed is the size to which samples must be crushed before the successive quartering operations are performed. He gives detailed results of many assays on a variety of ores, the mine samples of which varied in quantity.

The point is absolutely demonstrated that the samples considered must be crushed finer than ¼ in. before a representative portion for assay can be quartered from them. The results from working on the ¼-in. product are so erratic that they are useless. The author advises that the size to which various ores must be crushed before the quartering process begins must be determined for each ore. But his general results on a wide variety of ores indicates that the required size lies somewhere between ¼ in. and 10 mesh. He advocates the use of a jaw crusher delivering a ¼-in. product; a second crusher reducing to 10-mesh; and a disk pulverizer as best adapted to the proper preparation of samples.

Stamp Mills.

Performance of Stamps.—In the *Journal* of the Chamber of Mines of Western Australia for August, 1912, Mr. W. R. DEGENBART gives details of the operation of a unit of two Holman pneumatic stamps working on a mixture of hard and soft ore. The screens are 12-mesh; horsepower consumed ranges from 30 to 34 hp per unit; drops per minute, 123 to 135; capacity of the unit 130 tons per day; consumption of shoes

0.248 lb. per ton ore crushed; consumption of dies, 0.199 lb. per ton; weight of shoes, 224 lb., weight of dies, 177 lb.; water used, 1200 gal. per ton of ore crushed. By comparison with gravity stamps, the two Holman stamps excelled the performance of 15 gravity stamps.

Recent Metallurgical Patents.

Copper.

Hydrometallurgical Extraction of Copper.—The extraction of copper from its unroasted ores is the basis of a patent granted to José Baxeres de Alzugaray, of New York City, who has assigned his process to the Midland Ores & Patents Company, of New York City. The principle of the process is the use of a solution of iron and copper chlorides together with an alkali chloride and hydrochloric acid. As an example of the application of the process the inventor takes an ore containing 2.5 per cent copper, 25 oz. silver and 0.25 oz. gold per ton and treats it with the following solution: Ferric and ferrous chlorides, 10 parts; cuprous and cupric chlorides, 2 parts; sodium chloride, 20 parts; hydrochloric acid, 20° B., 4 parts; water, 64 parts, and sodium manganate, 0.1 part. Under the action of this solution the copper and silver will be converted into chlorides and held in solution. The oxidizing action of the sodium manganate will liberate chlorine which will attack the gold, and will also regenerate ferric and cupric chlorides after their action on the ore. By the addition of small amounts of oxidizing agent the solution is kept at its full strength, and after precipitation of its contained copper, silver and gold by suitable means it can be used again as a solvent for further metals. (1,041,407, Oct. 15, 1912.)

Process of Roasting Copper Ores for Extraction by Water.—In a patent granted to Mr. Utley Wedge, of Ardmore, Pa., the inventor discloses his proposed means of roasting ores containing copper oxide, carbonate or silicate in the presence of sulphurous gases, whereby the copper is converted into copper sulphate, which may be washed out by water. From the solution thus obtained the copper may be precipitated in any desired manner. The preferred form of furnace for the operation is a muffle furnace of the superposed-hearth type designed by the inventor.

In operation, the ore is fed into the furnace on the top hearth, and sulphurous gas is admitted at the bottom hearth or any other that may be preferable. The gas should contain not less than 3 per cent by volume of SO_2, and preferably 14 to 16 per cent. Some oxygen will have to be admitted with the gas to permit of conversion of the copper ores into copper sulphate. The temperature should be maintained at from 800 deg. to 1100 deg. F., and care should be taken to prevent so high a temperature that the formed copper sulphate will be decomposed. An effective manner of carrying out the process is to use it in connection with an ordinary roasting furnace, the hot sulphurous gases from which can be conducted directly into the furnace in which the copper ore is being treated. (1,043,400, Nov. 5, 1912.)

Alloy.—**Jesse Jones,** of Wilmerding, Pa., assignor to Westinghouse Electric and Manufacturing Company, claims the following alloy to have an "exceptionally high degree of resistance" to any and all strains to which it may be subjected: 51 to 64 parts of copper; 35 to 45 of zinc; 1/6 to 15 of a hardener, specified below; ⅓ to 3 of tin, and 1/6 to 8 of an aluminium, when the composition is required for casting. The hardener consists of tin, ferromanganese and magnet or high-speed tool steel or some other special steel in the proportion of 30:7½:62½ by weight. (998,777, July 25, 1911.)

Zinc.

Improved Retort Furnace.—In order more effectively to heat zinc retort furnaces of the type in which the exit flue for the products of combustion is placed at one end of the furnace chamber, Mr. Charles A. H. de Saulles, of Gas, Kans., has patented an improved design, which is illustrated in section in Fig. 1. In furnaces of this type the retorts *d* are supported on front and rear walls, the latter being also walls of a down-take *b* connecting with a flue and stack *C*. Gas and air for combustion are introduced into the muffle chambers through a series of ports.

It will be understood that the draft of the stack *C* on the air and gas ports will vary progressively from one end of the chamber to the other, causing non-uniformity in the heating of

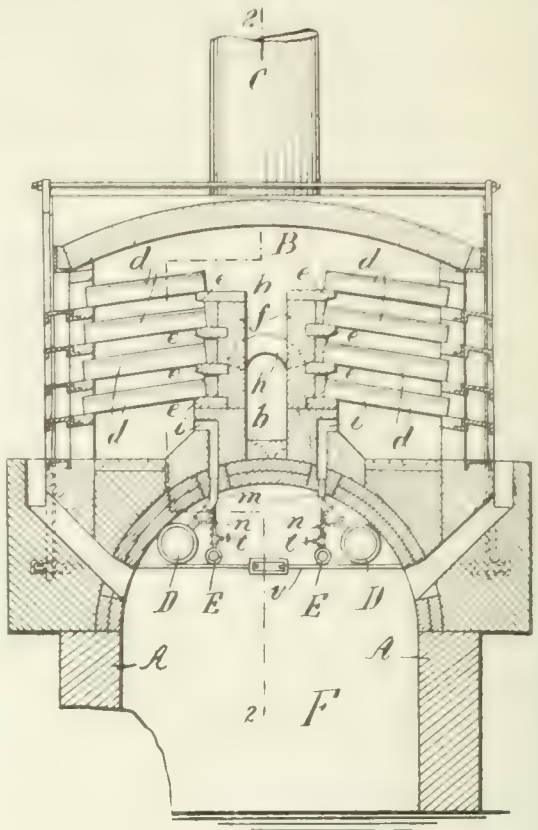

FIG. 1.—ZINC RETORT FURNACE.

the retorts in different parts of the furnace, and thus affecting the regularity and efficiency of the smelting operation. The present invention is designed to overcome this difficulty so as to permit the retorts in all parts of the furnace to be heated uniformly, and thus enable the smelting charge in different parts of the furnace to be worked off in the same period of time. To this end the inventor supplies his furnace with air and gas under pressure, delivered through the main pipes placed under the heating chamber. The gas main is shown at *E* and the air main at *D*. Branch pipes from each main conduct the air and gas to ports placed horizontally, in pairs, as shown at *i*. Each of the branch pipes is controlled by a valve, as at *n* and *t*. By appropriately adjusting these independent valves according to the pressure of the air and gas in the mains and according to the draft of the stack, it is possible to realize with substantial accuracy equalized conditions of temperature throughout the length of the combustion chamber. (1,041,977, Oct. 22, 1912.)

Treatment of Refractory Zinc-Lead Ores.—A patent has been issued to Mr. Andrew G. French, of Nelson, B. C., on a process for treating zinc-lead ores which are refractory to known methods of separation and recovery by methods of concentration and smelting. The essential feature of the proposed method is the conversion of all the zinc into a sulphate by heating with niter cake, or sodium bisulphate. This will render the zinc soluble, in which condition it can be separated from the lead and recovered in any manner, as by electrolysis. The ore must first be roasted, after which it is mixed

with the ground niter cake in a quantity varying from 5 to 15 per cent of the original weight of the ore. This mixture is then brought to a dull red heat in a reverberatory furnace. The reaction occurs quickly, and the product remains in a loose pulverulent condition. It is then leached with water and washed with a solution of sodium bisulphate, whereby the zinc sulphate is dissolved and can be separated from the lead sulphate. (1,041,060, Oct. 15, 1912.)

Recovery of Zinc from Galvanized Articles.—The recovery of zinc from galvanized-iron scrap may be accomplished by treatment with a solution containing a mixture of alkali bisulphate and a chloride of a metal whose hydroxide has an alkaline reaction. According to a patent granted to EDUARD BROEMME, of St. Petersburg, Russia, and RUDOLF STEINAU, of Nuremberg, Germany, 100 kilos of galvanized iron scrap of 9 per cent zinc is boiled with a solution of 20 kilos sodium

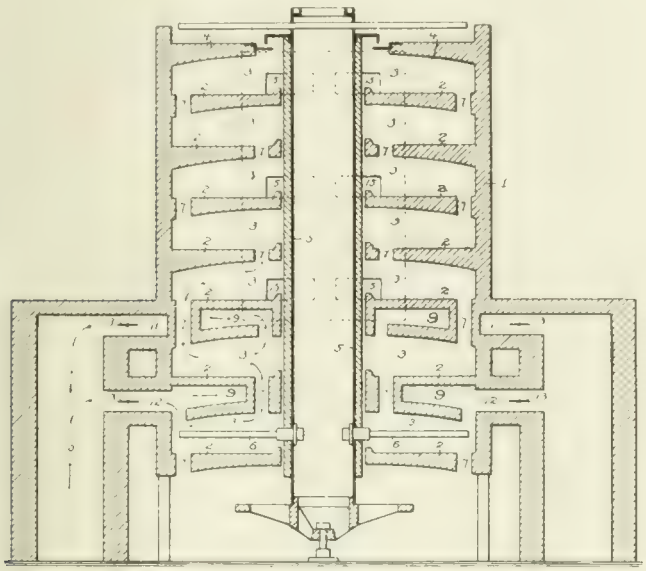

FIG. 2.—ROASTING FURNACE WITH HEATING CHAMBERS.

bisulphate and 20 kilos of common salt, until all zinc has gone into solution. This will result in a very pure solution containing zinc chloride, sodium sulphate and sodium chloride, containing only traces of iron and manganese, which can be used for the production of lithophone. The sodium bisulphate and salt react to form sodium sulphate and to liberate hydrochloric acid which attacks the zinc, forming zinc chloride. The zinc-lye thus obtained can then be treated with barium sulphide, whereby the following reaction will occur:

$$ZnCl_2 + Na_2SO_4 + BaS = ZnS + BaSO_4 + 2NaCl.$$

The resulting precipitate can be used directly for the manufacture of lithophone-white. (1,042,315, Oct. 22, 1912.)

Metallurgical Furnaces.

Roasting Furnace with Heat-Equalizing Chambers.—In Fig. 2 is shown a design of multiple-hearth roasting furnace patented by MR. UTLEY WEDGE, of Ardmore, Pa., in which the products of combustion are applied directly to material under treatment. The feature of the furnace is the heating chambers 9, the purpose of which is to maintain an equal heat, and to regulate the temperature in the different roasting chambers of the furnace. The superposed hearths are shown at 2, and the hearth-chambers at 3. The furnace has a central rotating shaft 5 provided with projecting arms and rabbles 6, shown only in the lowermost hearth-chamber. In order to make the heat more equable throughout the furnace, the heating chambers 9 are connected with the fire-boxes 10 by flues 11 and 12. A portion of the products of combustion pass from the fire-boxes through the flues into the heating-chambers as well as into the hearth chambers, as shown by the arrows. For the further regulation of the heat in the treatment-chambers, gas outlets are provided as shown at 15, which are adapted to be opened or closed as conditions may require. If, therefore, the temperature in the upper hearths is too high, a portion of the gases may be drawn off through the gas-port in a lower chamber. (1,040,071, Oct. 1, 1912.)

Channel Furnace.—In our issue for October, 1912, page 659, we published a description of a new process for the manufacture of alumina, hydrochloric acid, caustic alkali and a

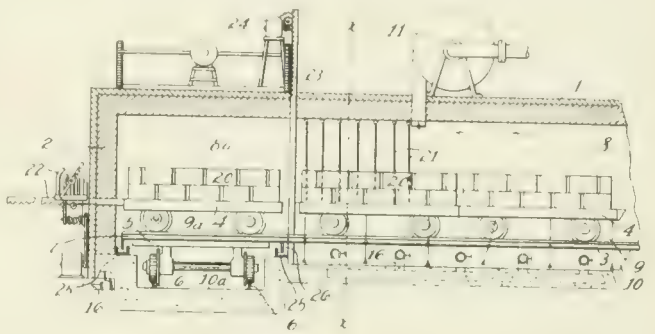

FIG. 3.—PORTION OF CHANNEL FURNACE AND VESTIBULE.

white hydraulic cement from salt, clay and lime. A feature of the process was the use of a tunnel or channel furnace, which has been patented by MR. ALFRED H. COWLES, of Sewaren, N. J., author of the article mentioned. The furnace, which is a modification of the Gronwall channel furnace, consists of a long tunnel or channel, provided with tracks over which are run cars carrying briquets of the mixture to be treated. Means are provided for preventing the deleterious gases which may be formed in the upper part of the furnace from penetrating below the body of the cars and attacking any corrodible parts of the cars and furnace. Fig. 3 shows a longitudinal section through a part of the furnace 1, together with the vestibule 2, into which the briquet-bearing cars 4 are run on a truck 5, before being pushed into the furnace by the pusher 22. The body of the furnace is divided into upper and lower parts 8 and 9 by the car bodies. The briquets of material are shown at 20. A suction fan 11 is placed at the top of the furnace near the entrance, for exhausting the hydrochloric

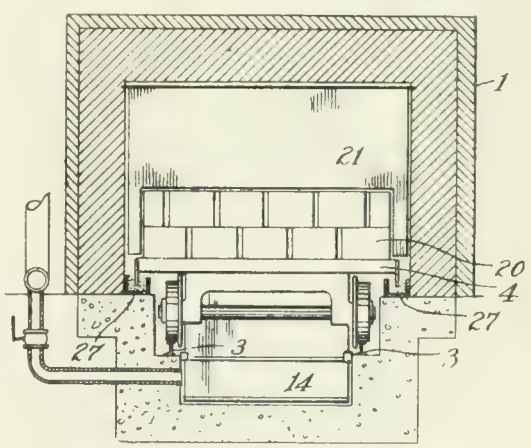

FIG. 4.—SECTION OF CHANNEL FURNACE.

acid gas produced by the reaction in the briquets. A blower also is provided to supply gas or air under pressure to the portion of the furnace below the car body. The branch air supply pipes are shown at 16. Baffles of sheet metal attached to the bottom of the cars divide the lower part of the furnace into a number of sections, while in the upper part of the furnace are hung a series of curtain baffles, fitting quite closely to the surface of the load on the cars. These baffles form a seal against the exit of the gases while the cars are traveling into the furnace. An adjustable door leading into the furnace

to the vestibule is shown at 23. Metal sheets fastened onto the sides of the car dip into a sand seal as shown at 25 in Fig. 7. The ends of the cars are made to fit as closely as possible, asbestos packing being attached to the end of each car.

Following is the application of the furnace in the manufacture of hydrochloric acid and alkali-silico-aluminate. The charge mixture composed of clay, salt and carbon, in the proportions, say, of 35 per cent to 65 per cent clay, 30 per cent to 50 per cent alkali chloride and 3 per cent to 10 per cent carbon, is briquetted and loaded on the cars and introduced into the vestibule. The vestibule is then closed and the door 23 of the furnace opened. By means of the pusher 22, the car is then gradually pushed into the furnace, forcing forward the cars already introduced, the mixture on which is undergoing conversion. While the car is being introduced into the furnace, the baffles above and below the car prevent the exit of any gases into the vestibule. Within the furnace the charge is subjected to the combustion gases which enter through the side walls of the furnace, and also to the action of steam and air which is blown into the furnace against the direction of travel of the cars. The chemical reaction of the charge evolves hydrochloric acid gas which is drawn off to a condensing system by the fan 11. This gas is kept in the upper part of the furnace by the devices already mentioned, where it is at a temperature of more than 220 deg. F., and therefore does not attack the iron of the cars. To prevent its ingress to the lower, or cooler part of the furnace below the cars, the blower is used to blow air into the portion of the furnace below the cars, and maintain a balance of pressure between the upper and lower parts of the furnace, or a slight upward pressure from the lower to the upper part. (1,040,895, Oct. 8, 1912.)

Iron and Steel.

Electric Steel Melting.—The literature on electric furnaces and the production of steel therein as contained in the U. S. Patents is abundant, very diversified, sometimes genial and sometimes full of commonplaces. There are two patents, however, recently granted to two men, both prominent in the field of electric furnace metallurgy, which are well worth studying. Both aim at the production of a more highly purified steel, each one in a different way, and both will give a decided impulse to practical operation no matter whether they will be carried out literally or with modifications.

Treatment of Molten Steel.—Prof. **Joseph W. Richards,** of Lehigh University, South Bethlehem, Pa., has already given a brief of his views while discussing a paper read before the recent International Congress of Applied Chemistry, as abstracted on page 603 of this volume of this journal. According to his ideas steel which has been finished by any of the well-known processes should be transferred to the electric furnace and held there in liquid state for a suitable length of time without adding any reagents such as are usually added to oxidize, deoxidize or otherwise refine it. The electric furnace will in this case merely be a "holding furnace," and among the objects attained by this "holding operation" may be catalogued the escape of gases, the floating up of impurities, the fixation of evolved impurities by union with the lining of the furnace, the completion of the intimate alloying of the ingredients of the steel, an increase in liquidity of the metal, and the exact regulation of the casting temperature. Twenty-nine different methods or combinations of methods of ordinary basic or acid steel making, and also including electric melting, are enumerated as processes preceding the final holding operation. Professor Richards prefers the induction furnace for use in this last step in the series of operations; he also prefers an acid-lined electric furnace and he apparently must be congratulated upon having solved the hitherto open problem of continually operating an induction furnace with an acid lining. (1,037,536, September 3, 1912.)

Manufacture of Steel is the title of a patent of the well known inventor, **Paul Girod,** of Ugines, France. His previous European patents dealing with the same subject have already been mentioned on p. 136 of Vol. 17, of the Transactions of the American Electrochemical Society (1910). Those who are both scientifically and practically interested in steel making know that during the cooling down of steel from the liquid to the solid condition there is a range of temperature at which the oxygen of the residuary oxides dissolved in steel acts on the carbon by forming CO. The evolution of this gas seems to evolve other gases simultaneously. Mr. Girod makes use of this phenomenon and claims to cool the steel transferred in molten state to the electric furnace down to 1250 deg. or 1300 deg. This is best effected by having cold scrap of the same or a purer composition in the furnace when the steel is poured in. In this process it is supposed that the steel has been dephosphorized in a preparatory furnace such as Bessemer converter or open-hearth, whereby the oxidation is carried less far than is hitherto common practice. A sufficient amount of oxidizable elements, such as about 0.10 to 0.15 per cent carbon, 0.1 to 0.2 per cent silicon and 0.2 to 0.3 per cent manganese, is left in the metal or is artificially added in cases where the circumstances required a more thorough oxidation of the bath. In being cooled down rapidly in the electric furnace this steel ejects gases up to the moment when the material becomes pasty. It is then reheated under a reducing slag, until the latter is entirely fluid, the remainder of the gases escapes and the alloying additions can now be made to tap and pour the steel. "Triple silicates of manganese, iron and silicon" are said to be instrumental in forming a readily fusible slag in the first phase of operations. (1,043,090, November 5, 1912.)

Open-Hearth Furnace.—Present open-hearth practice requires to shut down the furnace for a cleaning of the slag pockets. Mr. **Horace E. Smythe,** of Pittsburgh, Pa. (assignor of the S. R. Smythe Company), avoids this inconvenience by certain new devices. In order to remove dust, fluxes, metallic substances and the like from the waste gases issuing from the furnace chamber the gases are led into small chambers with inclined sole arranged at the bottom of the downgoing gas flues. From here they pass into the slag pockets, moving downward through these and entering the checker chamber from below. The checker chamber itself is divided into two unequal parts: the one entered by the waste gases first is the smaller one. After rising upward the gases reach the arch of the checker chamber extending uninterruptedly over both parts and pass downward in the usual way through the main part of the checker work. This arrangement allows the bulk of the impurities carried away from the furnace to accumulate in the first named auxiliary chamber with inclined bottom. A tapping device facilitates air removal from here without interrupting the operation of furnace. The slag pocket itself only needs to be cleaned out in longer intervals and any dust which should be carried beyond the slag pocket can still settle in the flues below the first part of the checker work. The latter is thus prevented from being clogged and an even heating of the air and gases guaranteed. (1,042,047, October 22, 1912.)

Soaking Pit.—Mr. **Horace E. Smythe** furthermore provides a soaking-pit top with means which will prevent its destruction by the intense heat within. The cover of the pit is divided into individual sections. A plunger or other moving device travels along the end of the cover sections and carries near each end a pivoted latch which may be swung so as to connect with lugs in any of the cover sections. The plunger can then be operated to open any desired part of the pit. Adjacent to the wheels which carry the covers is an inclined track which causes the cover to rise as it moves from over the opening, and means are provided permitting the axles of the wheels to move downwardly after the cover is seated on the furnace. (1,044,093, November 12, 1912.)

Non-corrosive Iron-Nickel Alloy.—Two patents issued to Mr. Robert B. Carnahan, Jr., of Middletown, O., refer to the very pure iron which has been placed on the market, as especially resistive to corrosion, by the American Rolling Mill

Company, of Middletown, O. According to his present patent he purifies molten iron to such an extent that its content of carbon, phosphorus, sulphur, silicon and manganese combined does not exceed 0.14 per cent, with oxygen reduced to not more than 0.05 per cent. He finds that the corrosion-resisting qualities of this iron may be still further increased by alloying with it a metal such as nickel, so that the finished alloy will contain, say, 99.30 per cent. iron, 0.50 per cent nickel, not more than 0.14 per cent carbon, phosphorus, sulphur, silicon and manganese combined, and not more than 0.05 per cent oxygen. The alloy may be made in an open-hearth furnace by first refining the iron to the condition indicated, adding the alloying metal and then pouring the molten mass into a ladle containing a deoxidizing agent, such as aluminium at the rate of 2½ lb. per ton. The proportion of alloying metal added will be determined by the use to which it is to be put, consistent with the cost of the nickel. If high cost is justified by the results, the inventor states that an alloy can be produced thus which will be practically proof against corrosion. (1,035,947, Aug. 20, 1912.)

Combination Process for Steel Manufacture.—With the intention of utilizing the best features of the open-hearth furnace, Bessemer converter and electric furnace, Mr. FRED B.

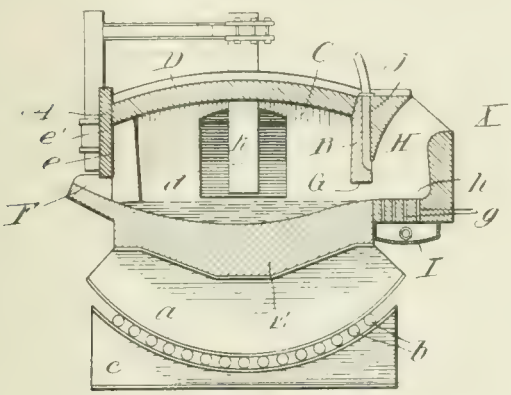

FIG. 5.—COMBINATION OPEN-HEARTH CONVERTER AND ELECTRIC FURNACE

LAMB, of Bettendorf, Ia., has patented a combination furnace. While the basic open-hearth furnace is adapted to the removal of carbon, silicon, manganese, phosphorus, and possibly sulphur, the operation is expensive and requires considerable time; and the baser the raw materials, the more difficult and more expensive does the operation become. On the other hand, the Bessemer converter has proved itself an excellent means of decarbonizing and desiliconizing; the basic open-hearth furnace excels in dephosphorizing; and the electric furnace has proved best in the removal of sulphur and as a deoxidizer. The inventor, therefore, proposes to combine all these features in a single tilting open-hearth furnace with converter and electric attachments.

The furnace is shown in three positions in Figs. 5, 6 and 7. It consists of the usual tilting-furnace structure, the curvature of the concave tracks being struck from the center of the gas port *d*, in the end walls of the furnace. The gas ports are provided with vertically movable gates which can be lowered and raised from the outside. The charging port is at *e*, which is normally kept closed by a door *e'*. The Bessemer converter consists of a chamber *H*, air-box *I* and air-passages *g*. An air-flue *J* also is provided at this part of the furnace, the function of which will appear later. Extending down through the roof of the furnace are electrodes *k*, which are adjustable vertically.

In operation, the furnace is charged with, say, 15 tons of pig iron. As the carbon content of the pig iron would be high, oxidation would commence at once, and the entire charge would be melted in about two hours. When about 5 tons of metal had accumulated in the bath, and after the blast had been turned on in the converter, the furnace would be tilted toward that end as shown in Fig. 6. This part of the metal would then be decarbonized and desiliconized, and its temperature raised from 1800 to 3000 deg. F. The highly acid slag which would be formed could then be poured off, the operation being facilitated by directing a blast of air through the flue *J*. The furnace would then be tilted back to a horizontal position as shown in Fig. 5. Due to the increased tempera-

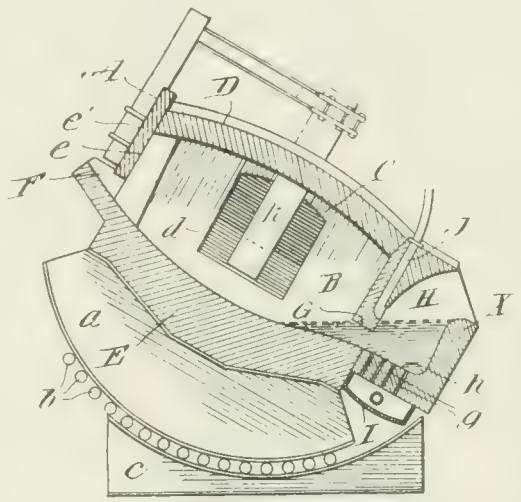

FIG. 6.—COMBINATION STEEL FURNACE AS CONVERTER.

ture of the 5 tons of metal which had been bessemerized, and its impregnation with oxidizing gases, the reduction of the unmelted portion of the bath would be hastened and its carbon oxidized. During this operation, dephosphorization has gone on without interruption, and at the end of about two hours the entire charge will be melted and its content of carbon, silicon and phosphorus reduced to the proper limits. Further the temperature of the bath will be at a high point. There remains then to be eliminated the occluded gases and the sulphur. The electric process is, therefore, now brought into play for the purpose of removing the gases and sulphur. The result of the combined processes is claimed by the inventor to be steel of the

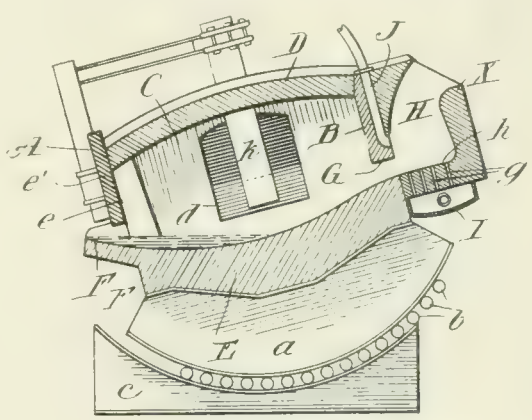

FIG. 7.—COMBINATION STEEL FURNACE IN POURING POSITION

highest grade obtainable, which may then be poured by tilting the furnace in the position shown in Fig. 7. (1,036,498-499-500, Aug. 20, 1912.)

Heating Furnace.—Heating furnaces of the "over-fired" type, that is furnaces in which the combustion takes place above the heating chamber and the fire gases are discharged downwardly from the combustion chamber into the heating chamber are regulated quickly and accurately with greater difficulty than direct-fired furnaces. In a furnace, for instance,

having a double arch which forms the combustion chamber, and flues rising in the side walls of the furnace from the bottom up into the main flue, the rising of the heat can be checked by closing the burner or by opening the door. The first means would not be effective at once in the heating chamber but for

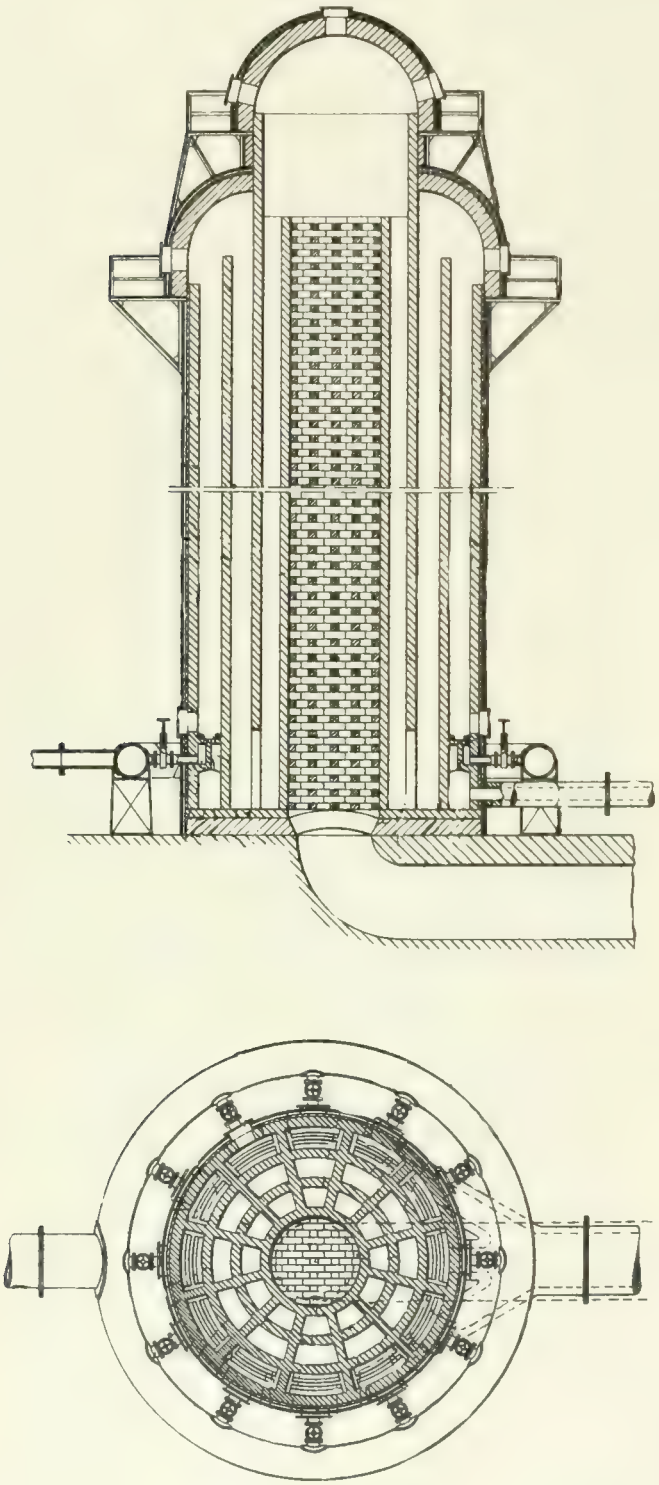

FIG. 8.—AIR-BLAST HEATER.

quite some time later on, the second would cool the furnace non-uniformly. Mr. **Wirt S. Quigley,** of Rockaway Park, N. Y., therefore controls the heat of such furnaces by providing a regulating relief passage in the top of the combustion chamber. This can be closed or partially or wholly opened. When opened it permits the escape of the heat from the combustion chamber without passing into or through the heating chamber. A drawing shows this invention as a hole in the roof covered by a damper plate. (1,039,801, October 1, 1912.)

Regenerative Reversing Furnace.—Mr. **Luther L. Knox,** of Avalon, Pa., supplies the parts of an ordinary open-hearth furnace most exposed to wear and tear by action of the heat with suitable water cooling devices. In his previous U. S. patent 973,943, of October 25, 1910, he has already shown the plurality of water-cooled plates of which his cooling device for the roof wall of the furnace consists. The same principle of hollow plates is now used for cooling, by means of separate top, side and bottom members, the gas ports of such furnaces, the gas and air uptakes and the side walls and door openings. A more detailed description would require quoting the entire text of the patent. (1,041,814, October 22, 1912.)

Regenerative Furnace for Tube Welding.—With the present type of welding furnace it is difficult to keep pace with the rapid production because the doors are partially open during most of the time and admit an excess of cold air; the heating is also non-uniform in the wide furnaces in which the flame has to pass too large a distance. Mr. **Peter Patterson,** of Pittsburgh, Pa., solves this problem by dividing each furnace into two smaller ones which can be handled by the same charging machine and by providing ample regenerators under these furnaces and gas flues under the hearth. The dividing wall between the two furnaces receives so much heat that it is cooled by a system of water pipes. One furnace can always be kept closed and serve as heating furnace while the other one is being discharged. (1,038,640, September 17, 1912.)

Air-Blast Heater.—Mr. **Edmund Hohmann,** of Stettin, Germany, has designed a new form of the air heaters in use in connection with blast furnaces. The majority of the air blast heaters now in use in Germany have the combustion chamber on one side of the checker work. This does not utilize the heat of the gases as well as the new nested design which is entirely symmetrical, having three annular flues outside enclosing a central cylinder of checker work which connects to the stack. The annular chambers are radially subdivided into sections. The hot furnace gases entering from the outside toward the center of the device and the heated air passing in the opposite direction cause a slower movement of the gases in the hotter parts of the heater where the sections are larger, and an increase of speed of the cooler gases which pass through the still colder or cooling-off sections. While the circular arrangement is shown in the accompanying Fig. 8, the inventor finally claims any sort of section. (1,038,887, September 17, 1912.)

Converter.—Mr. **Alexander F. S. Blackwood,** of Detroit, Mich., has designed a Bessemer converter which can be more readily repaired than is ordinarily the case with converters. The characteristic feature of the new type is that it consists of two parts which can be easily joined together and separated, the separating plane passing just through the locality at which the maximum wear of the lining of the converter occurs. According to illustrations this line runs right above the trunnion ring. After loosening holding shackles the upper portion of the converter can be lifted up by a crane, thus enabling the bricklayer to repair the lining after but a few hours of cooling, whereas from 15 to 18 hours are commonly required before a man can enter into it to repair the lining. This arrangement reduces the number of converters required to produce a certain output. (1,042,876, October 29, 1912.)

Furnace Top.—A new variety of charging device for blast furnaces by **Frank C. Roberts,** of Wynnewood, Pa. See our September issue, p. 554, U. S. P., 1,033,036. (1,033,034 and 1,033,035, July 16, 1912.)

Crucible Furnace.—Mr. **Wilhelm Buess,** of Hanover, Germany, has designed a new means of heating a filtable crucible furnace using liquid or gaseous fuel. Opening 39 of the accompanying drawing shows the entrance of the flame, the diametrically opposite opening 40 with lid 41 is an emergency discharge of gases and of liquid material from broken crucibles.

Chamber 17 below the bottom of the furnace is kept cool by passing the pressed air of combustion through said chamber and preheating the air. When the air is hot enough it can also be switched over to the burner direct without passing through chamber 17. The other features of the furnace are self-understood from Fig. 9. (1,044,012, November 12, 1912.)

Reduction of Ores.—By a process, somewhat similar to the Talbot process of reducing iron ore in a tilting open-hearth furnace, the well-known electrical inventor Dr. **Elihu Thomson** proposes to produce iron or steel direct from ore. By using, for instance, a basic-lined converter, he melts down a bath of iron and introduces a blast of ordinary or of enriched air to

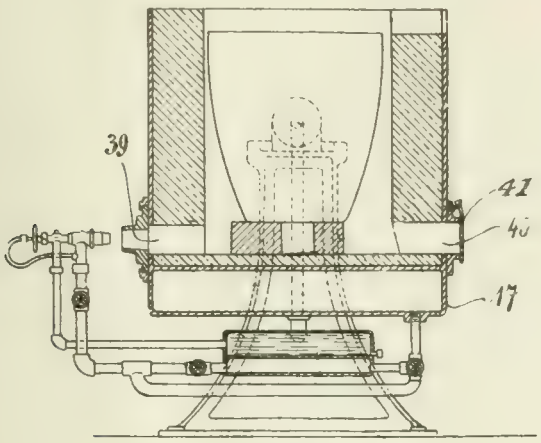

FIG. 9.—CRUCIBLE FURNACE.

thoroughly oxidize the iron to the magnetic oxide state. By using air enriched in oxygen a higher temperature is reached. The nitrogen is carried off for other uses by means of appropriate conveyors; its heat can be utilized to preheat the raw materials which are used during the next stage of the process. A mixture of ore and carbon with suitable slagging agents are now introduced into the liquid bath, the carbon being in such amount as to take care of the combined oxygen in the ore and in the liquid bath. It may also be charged in excess when it is desired to increase the heat by the oxidation of the carbon. This stage of the process produces metallic iron and carbon monoxide in a nearly pure state, which is suitable for utilization in gas engines, for heating, etc. Part of the charge is then poured off and finished by the proper addition of ingredients, as soft iron for steel. The remainder of the charge is oxidized as before, and the circle of operations begins anew. (1,031,490, July 2, 1912.)

Treating Ores.—Mr. **Edward Kerr,** of Pittsburgh, Pa., describes a method of treating ore, more particularly iron ore, alternately with superheated steam and air in a muffle furnace and then separating mechanically (by a magnetic separator) the metallic portion of the charge from other solid constituents. The muffle is externally heated by passing products of combustion through flues below the bottom and above the arch. Between the bottom flues tubes are arranged with nozzles in the bottom of the furnace through which steam and air are directed into the charge. The forcing of steam and afterwards of air into the pieces of ore disintegrates the same, and the metallic parts after being separated from other solid ingredients can be mixed with carbon and molten in the usual way. They can also be mixed with a suitable binder and first pressed into blocks. (1,032,007, July 9, 1912.)

Method of Producing Practically Pure Iron.—The wooden poles are familiar implements in copper refineries. **Archibald Smith,** of Tarentum, Pa., assignor to the Allegheny Steel Company, makes use of sticks of spruce or other coniferous woods to refine steel in an open-hearth furnace. Carbon, manganese, phosphorus, sulphur, silicon and oxygen are removed from the bath to the greatest possible extent by the application of heat, fluxes and reagents, according to the well known basic open-hearth process. During this treatment sticks of wood are forced below the surface of the metal bath and after they are consumed are replaced by others until the violent agitation and ebullition of the bath which ensues has ceased. By this process the bath is deoxidized without increasing the carbon content. This highly purified product will solidify without blowholes or spongy top, is less susceptible to corrosion than any other known iron, highly malleable and ductile, etc. (1,008,377, Nov. 14, 1911.)

Iron-Silicon Ingot (Rustproof Iron).—Ordinary Bessemer and open-hearth steels rust more than wrought or puddled iron. The manganese, used as a deoxidizer, is apt to segregate and increase the rate of corrosion. **Eugene A. Byrnes,** of Washington, District of Columbia, assignor to Pittsburgh Pure Metal Products Company, therefore proposes to manufacture, preferably in the basic open-hearth, a product containing up to 99.7 per cent iron, not over 0.15 per cent total carbon, sulphur, phosphorus, manganese, oxygen and nitrogen, and 0.15 per cent or more of silicon. The temperature of the furnace is kept high. The combined oxygen is then removed by silicon (used as 50 per cent alloy) and titanium (in the form of a 30 per cent alloy). Silicon is added in sufficient excess to leave from 0.10 to 0.15 per cent in the finished product, titanium preferably in the minimum amount necessary to eliminate oxygen and nitrogen. In some cases it may be desirable in order to obtain a high temperature and facilitate the final reaction, to tap the metal into an electric furnace, thereby largely removing the slag in transit. (1,004,987, Oct. 3, 1911.)

A New Type of Rotary Gas Producer.

The announcement of several large gas producer contracts recently awarded the Chapman Engineering Company calls attention to a radically new type of gas producer which is the invention of Mr. W. B. Chapman, of 11 Broadway, New York City. It is manufactured by the C. & G. Cooper Company, of Mount Vernon, Ohio, who are also largely interested in the Chapman Engineering Company.

The Chapman rotary gas producer, as shown in the accompanying illustration, performs three distinct operations, one for each of the three steps necessary to the process of making producer gas, viz.:

1. Mechanical feeding and spreading the fuel.
2. Mechanical agitation of the entire firebed.
3. Mechanical removal of the ash.

These, in brief, are the three fundamental ideas around which this producer is built, and in its design the solution has been found for the complete mechanical control of all three of these necessary steps.

Automatic Feed.

The first unique feature of this producer is that its "mechanical" feed has no mechanical parts.

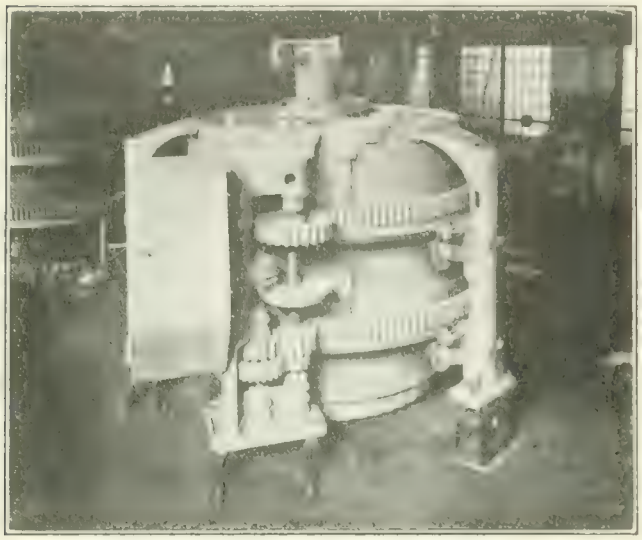
Another feature is that fine and coarse coal are handled simultaneously without separating the coarse from the fine. Heretofore in mechanical feeds a spout or bell has usually been resorted to with the result that the fine fuel was liable to drizzle off from the end of the spout into the center of the producer, while the coarse fuel bounded from the spout with sufficient force to carry it to the walls, the result being a separation of the fine from the coarse coal in the fire bed, very much to the detriment of the operation of the producer. With the Chapman feed this separation is made impossible.

The fuel chamber is stationary and has no bottom. It has a capacity of 1000 lb. of coal—enough to last for half an hour. The lower edge is water-cooled. As the revolving fire bed comes under the chamber, a fresh supply of fuel is spread over the surface, thus constantly keeping the level of the fire bed up to the bottom of the fuel chamber.

The lower edge of the fuel chamber is beveled so as to pro-

duce a down-stroking effect upon the fire bed as it passes under it, thus "rubbing in" the fresh fuel.

An interesting feature of the Chapman feed is that it is the only one that will feed the coal in unevenly as conditions require. Heretofore the effort has been to drop the coal evenly over the fire bed. Logically, however, the coal should be fed into the producer unevenly, not evenly; for obviously when holes and crevices start to form in the surface of the fire bed



[illegible] CHAPMAN ROTARY GAS PRODUCER

more coal is required at these points than elsewhere.

The fuel chamber also prevents a rush of soot into the flues each time fresh fuel is charged into the producer. The tarry gas first given off from the coal in the fuel chamber must pass down through the hotter fire at the bottom of the chamber before it can escape to the flue. This reduces the amount of tarry smoke in the gas.

The Illinois Steel Company made a continuous test of this feed for the month of August, 1911, at their works at South Chicago. As compared with the operation of the hand-poked producers at this plant, this test showed the following results:

1. An increase of 19.1 per cent in the strength of the gas.
2. A decrease of 42 per cent in the quantity of steam required per ton of coal gasified.
3. The elimination of 83 per cent of the soot deposited in the flues.

After nine months' trial of this machine they ordered four more.

Agitating Without an Agitator.

The second distinctive feature of this machine is the means used for agitating the fire bed. Some years ago the Chapman company discovered that the best method of agitating a gas producer was to revolve one-half of the fire bed over the other, thus setting up a twisting and shearing action throughout the entire fire bed. The producer is therefore divided horizontally through the hot zone into an upper, and lower section, and the two sections are made to revolve in the same direction, but at different speeds.

Each section of the wall carries with it that portion of the fuel bed which it surrounds. Thus the maximum amount of agitation is produced through the hot zone where it is most required. The unique feature of this second step in the process is that adequate agitation is obtained without recourse to an agitating member.

Agitating arms or beams are limited in their action to a comparatively small portion of the fire bed at any given time, thus leaving the balance of the fire bed to become disorganized. It is claimed that agitating members in the fire bed leave in their wake a gap or recess detrimental to the operation of the

[illegible] producer, and they burn off in about six months in spite of [illegible] water-cooled. If they protect only the hottest portion of the fire

Prevention of Clinkers.

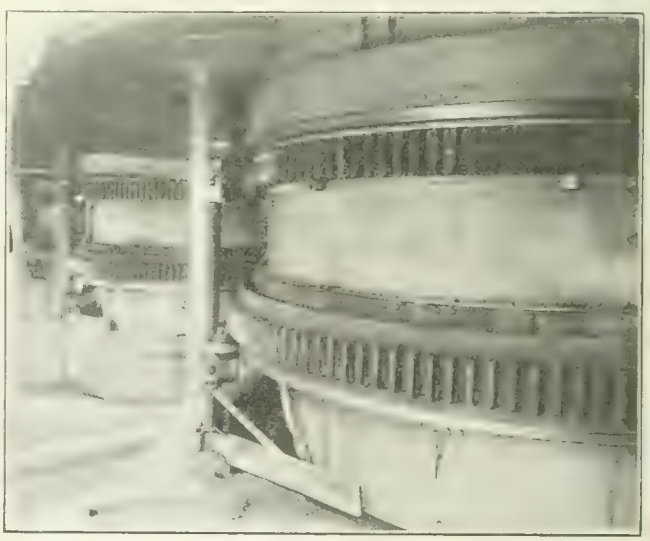
The chief difficulty in manufacturing producer gas is the prevention of clinkers. Clinkers are caused by excessively hot spots in the fire bed. These hot spots are caused by uneven spreading of the coal, or uneven agitation of the fire bed, or uneven distribution of the air blast, or uneven removal of the ashes. Uneven conditions in a producer make blow-holes, chimneys" or "pipes" in the fire bed. If left alone these holes become rapidly larger, and the temperature about them increases until the fusing point of the ash is reached. Clinkers then start to form about each of these hot spots, and when once formed, it is a matter of considerable difficulty to remove them. If the excessively hot spots are avoided and the uneven conditions prevented, there will be no clinkers.

In the Chapman producer the twisting of the upper half of the fire bed over the lower shears off the holes as fast as they tend to form. This action together with the fuel spreader and the continuous ash removal effectually prevents the formation of clinkers.

This freedom from blow-holes in the Chapman producer is evidenced in the unusually low temperature of the gas (about 1200 deg. Fahr.) and also in the lack of soot. So small is the amount of soot made that the Chapman Engineering Company have recently been able to enter into a contract guaranteeing that an installation of three of these producers will operate continuously for two months without requiring a shut-down for flue cleaning.

Ash Removal.

The last step in the process of making producer gas, that of removing the ash, is accomplished in this producer in an equally novel manner. The ashes are first ground between the sides of the stationary corrugated air box or "ash crusher" and the revolving corrugated wall of the lower section. In mechanical producers the crushing of the ashes is a very necessary preliminary to their removal, as otherwise an occasional large chunk would block the operation. After the ashes have been crushed they are forced up to the top of the ash pan by three



[illegible] INSTALLATION OF CHAPMAN ROTARY GAS PRODUCERS IN STEEL PLANTS

adjustable ash plows. These three ash plows are kept continually in operation, and are easily adjusted when occasion requires, which is not often.

As fast as the ashes are lifted to the surface of the water in the ash pan they are automatically scooped up and carried to the required point for automatic discharge. The fact that the ashes in being removed are removed upward instead of down-

ward makes a saving of several feet in the height required for the gas house and foundation.

There is little or no advantage in removing the ashes mechanically if they cannot be removed continuously. Heretofore all mechanical ash removing devices have been intermittent, operating for possibly an hour once or twice in twenty-four hours. This invariably resulted in a badly disorganized fuel bed, requiring several hours to rectify. The ash-removing device in the Chapman producer is the first to fill this important requirement of being continuous.

Capacity.

As a result of the joint action of the automatic fuel spreader, the twisting of the fire bed, and the continuous removal of the ash this producer may be made to gasify a ton of coal an hour

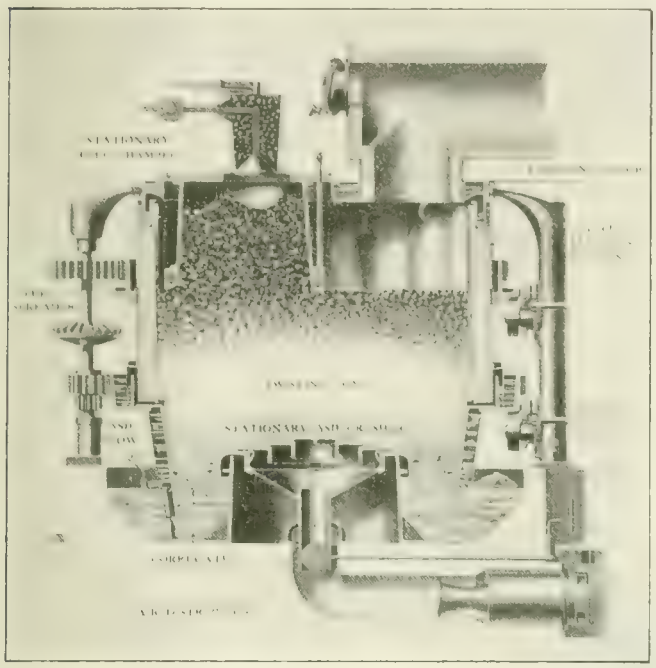


FIG. 3.—SECTIONAL VIEW OF CHAPMAN ROTARY GAS PRODUCER.

—at least twice the capacity of the ordinary hand-operated producer, and at the same time the quality of the gas is greatly improved and more uniform.

Record at Cleveland and Youngstown.

In ordinary practice with the old-style hand-operated producers the gas usually varies about 20 per cent in strength during each day, while the weekly variation is usually over 40 per cent. The Chapman Engineering Company believe they have established a new record for uniformity of gas production. The greatest amount of variation in a two-weeks' test at the Consolidated Works of the American Steel & Wire Company, in Cleveland, was only about 2½ per cent. At this plant three producers have been in operation since November, 1911, one of them (the first order) has been in operation two months longer. The average results of a two-weeks' test, conducted by the American Steel & Wire Company, in April, 1912, at this plant showed the following gas:

ANALYSIS.

Combustible	B.t.u.	CO_2	ILL	O	CO	H	CH	H
42.22	150.8	0.54	0.51	0.31	21.01	17.1	2.70	50.90

The greatest variation from the average of 150.8 B.t.u. was but 2.54 per cent, the poorest gas having 147.34 B.t.u. and the best 154.6 B.t.u.

A similar producer has been in operation at the plant of the Youngstown Sheet & Tube Company, Youngstown, Ohio, for nearly two years with even better results than the above. The CO_2 has averaged between 4 and 7 per cent and the CO between 20 and 25 per cent, while the B.t.u.'s have kept close to 160.

The Youngstown Sheet & Tube Company has recently awarded contracts to the Chapman Engineering Company for five additional producers.

As a result of their investigation of the Chapman producer at the Youngstown plant, the Brier Hill Steel Company, of Youngstown, placed an order a few months ago for twenty-two of these machines for their new open-hearth furnaces and soaking pits.

The details of this machine have been worked out with unusual care; no expense seems to have been spared and the result resembles Corliss engine practice rather than gas producer construction. For example, the following is rather unique construction for a gas producer:

The supporting rollers run on high-carbon steel pins and are provided with brass bushings. These rollers are cast in a chill and ground. Separate rollers are used to take the side-thrust; all rollers are mounted in pairs set in equalizing yokes; all bearings are provided with large oil wells filled with waste after the manner of railroad cars. The faster gears run in oil. Steel castings are used extensively both in the gears and throughout the balance of the construction.

Six years of continuous effort were put upon this producer before it was ready to be placed upon the market.

An Improvement in Screw Conveyor Design for Abrasive Materials.

In the handling of cement products, ashes, or other abrasive materials, with screw conveyor, delays and expense are caused by the necessity for renewals, because at each journal bearing where the flights are discontinued there is an obstruction offered to the flow of the material along the trough by the journal bearing support or hanger, and the interruption of the conveying spiral at that point. This tends to accumulate material and imposes extra work on the end-flight in pushing it past the bearing into the path of the next section.

Experience shows that this extra work wears away the end of the delivery flight and its outer edges, until the accumulation extends back farther and farther from the bearing, thus losing efficiency for the conveyor and finally forcing the renewal of the whole section.

The end-flights may be practically worn away, while the rest of the conveyor may show but little wear. Thus Fig. 1

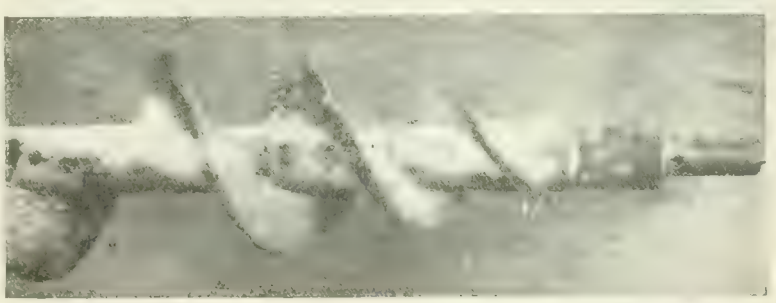

FIG. 1.—WEAR OF ORDINARY END FLIGHTS AFTER 3 WEEK'S SERVICE.

shows the results of wear after three weeks' service in handling cement clinker with ⅝-in. standard reinforced steel flights. Heretofore when a coupling gudgeon wore down in this way and needed renewal, it required considerable work to remove and replace the old gudgeon, and the shut-downs necessary for renewals of conveyor sections and coupling gudgeons caused serious interruptions.

This difficulty has been overcome successfully by a clever invention of the late D. D. Drummond, vice-president and

general manager of the Chicago Portland Cement Company. Mr. Drummond's invention makes renewals easy, and furnishes end flights made of material which is high in wear-resisting properties. The end flight, generally made of manganese or other hard and tough steel, has a center or hub whose recess is large enough at one side to receive the end of the conveyor shaft or pipe, and small enough at the other side to fit the end of the coupling gudgeon. The adjacent gudgeon ends of the two end-flights are provided with removable caps which permit the coupling gudgeon or the end-flights to be taken out or replaced without disturbing the rest of the conveyor. As

FIG. 2. DRUMMOND END-FLIGHT AND COUPLING GUDGEON ASSEMBLED.

the end flights are secured to the gudgeons and to the conveyor shafts or pipes by bolts, it is a simple matter to make renewals when necessary.

Fig. 2 shows the Drummond end-flights with coupling gudgeon assembled complete. The removable cap is omitted from the right end to show detail of arrangement.

The improvement obtained with this device is remarkable. In the same service which wore out the ⅝ steel flights of Fig. 1 in three weeks, the Drummond end-flight stood up well and its condition is shown in Fig. 3 after six months of this severe service. Careful measurement showed only ¼-in. wear

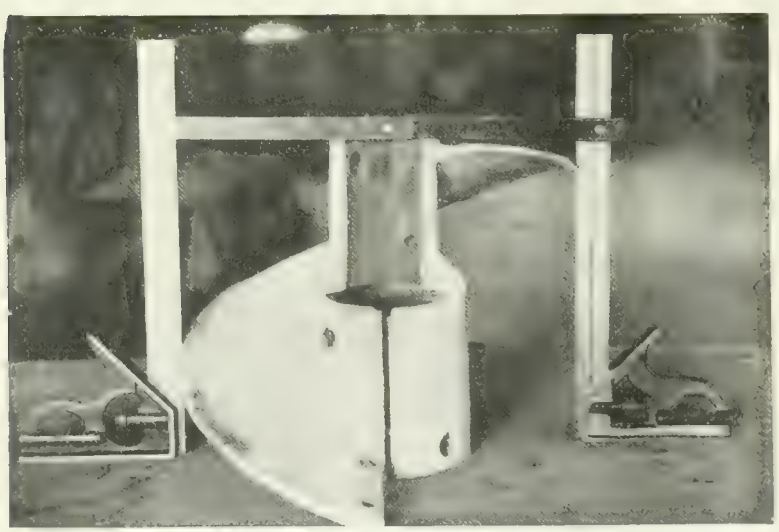

FIG. 3. DRUMMOND END-FLIGHT AFTER 6 MONTHS OF THE SAME SERVICE AS FIG. 1.

on the outer edges (or ½-in. total diameter). The delivery end of the flight was worn thinner, but was still intact, and the opposite end had full thickness.

After the device has proven its reliability and success in actual severe practice it is now being placed on the market by the Link-Belt Company of Chicago, Philadelphia and Indianapolis.

The London *Electrical Review* celebrated its fortieth birthday in its issue of November 15. The first issue appeared on November 15, 1872, the title being *Telegraphic Journal*. The words *and Electrical Review* were added in 1873.

Personal.

Mr. **Cyril J. Atkinson,** the inventor of the Atkinson gas producer, has severed his connection with the Dornfeld-Kunert Company of Watertown, Wis. Mr. Atkinson's services and the use of all his patents have been secured by Fairbanks, Morse & Company, of Chicago, and a number of Mr. Atkinson's inventions will be incorporated at once in the Fairbanks-Morse gas producers.

Dr. **Gustave Drobegg** has resigned his position with Charles Pfizer & Company, with whom he had been [illegible] twenty-five years, and is now associated with Mr. [illegible] proprietor of the Standard Scientific Laboratories, as chief chemist of the manufacturing laboratories.

Dr. **Paul Héroult** sailed for France on November 23rd with the steamship "La France" for a stay of several weeks.

Dr. **Hugo Lieber,** general manager of the Blau Gas Company, has returned on the "Kronprinzessin Cecilie" from his European trip.

Mr. **Robert Woolston Hunt** will be the guest of honor at the reception to be tendered to him by the American Institute of Mining Engineers, the American Society of Mechanical Engineers, and the American Institute of Electrical Engineers, on the evening of December 5th, at the Engineering Societies' Building. The John Fritz Medal for 1912 will be awarded to him on this occasion by the Board of Award, consisting of representatives of the four national organizations of the civil, mining, mechanical and electrical engineers. The medal is awarded to Mr. Hunt for "his contributions to the early developments of the Bessemer process."

Mr. **L. E. Saunders,** who has been in charge of technical and research work for the Norton Company, manufacturers of abrasives and refractories, at its alundum plant at Niagara Falls, N. Y., and its crystolon (silicon carbide) plant at Chippewa, Ontario, has been made general superintendent of the two works in addition to his former duties. No change in the personnel at the two plants will be made at present except the transference of Mr. S. F. Hull, who has been associated with Mr. Saunders as operating superintendent, to the main works of the Norton Company at Worcester, Mass., where he will be plant engineer.

Mr. **B. Viola** has resigned as managing and chief engineer of Messrs. Chas. Pfizer & Company, with whom he was associated for sixteen years, and will open a consulting engineer's office for the equipment and installation of chemical and allied industrial works and power plants.

Mr. **Hugh M. Wilson,** first vice-president of the McGraw Publishing Company, has been elected president of the American Trade Press Association of New York.

Coal Miners.—The total number of men employed in the coal mines of the United States in 1911, according to the United States Geological Survey, was 722,335, of whom 172,585 were employed in the anthracite mines of Pennsylvania and 549,750 in the bituminous and lignite mines. The anthracite miners averaged more working time than the bituminous miners, working 246 days, against 211 days for the bituminous miners. The average production for each man employed was 524 tons in the anthracite mines—an exceptionally large tonnage—and 738 tons in the bituminous mines. The average daily production for each man employed was 2.13 short tons in the anthracite and 3.50 tons in the bituminous mines. In most of the bituminous mines of the United States the 8-hour working day prevails. In 1911, out of a total of 549,750 employees in the bituminous coal mines, 330,045 worked 8 hours a day.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (*Continued*).

619,349, Feb. 14, 1899, Hugo Riecken, of London, England.

Relates to the electrolytic extraction of precious metals from ores or slimes by the solution of the precious metal from the ore and its deposition upon mercury in an easily-recoverable condition.

I employ a vat having a suitably shaped converging bottom and vertical or inclined sides lined with copper which may be silver plated, connected as cathodes. At the lowest point of the lining there may be arranged a gutter for the reception of mercury and near the upper edge of the lining is a pocket or trough extending wholly or partially around it and having openings or a slit over the metallic surface. The mercury is withdrawn from the bottom of the vessel through a tap and delivered into the pocket or trough near the top, whence it escapes through the slit or holes and descends in streams over the lining back into the gutter, a circulation of the mercury and a continuously-changing cathode surface being thus maintained. The anode is composed of rods or plates of carbon, metal, etc., fixed to a shaft, which is suitably rotated or oscillated to agitate the ore.

The slimy ores may or may not be first mixed to a pulp and introduced into the vat, which contains a suitable electrolyte, e. g., a weak solution of cyanide of potassium to which may be added a salt such as sodium chloride, which under electrolysis yields oxygen or an equivalent oxidizing agent to accelerate the solution of the gold, etc. The pulp is kept agitated by the anode stirrers and the anion which is generated at the anode gradually dissolves the precious metal, which, together with the potassium, is deposited upon the cathode and both amalgamated. If the gold in the ore is in a finely-divided state and soluble in the electrolyte without the aid of electrolysis its solution will be greatly accelerated by the use of the stirrers and the current will then deposit the gold. When the operation is completed the vat is opened and the finer slimes run out to settle. Any gold amalgam which may be found among the coarser particles may be separated on the concentrating table, the recovered amalgam being treated in the ordinary manner.

623,822, April 25, 1899, Louis Pelatan, of Paris, France, assignor to the General Gold Extracting Company, Limited, of London, England.

Relates to apparatus for use in the treatment of ores, sludges, pulps, solutions, or the like, containing gold or silver or both so as to obtain the precious metal in a more complete and satisfactory manner and with economy of the agents employed in the treatment. It contains a reference to his application for the process, which became patent 627,422.

Within a vat of any suitable material, such as wood, cement, etc., a revolving anode is suspended by a shaft, the anode having arms, the lower surfaces of which may be provided with anode-plates such as carbon, iron or steel, and which are parallel to a layer of mercury, constituting the cathode, on the copper, iron or cement bottom of the vat. The shaft is in metallic connection with the anode and completes the circuit through a brush contact; it is so mounted in its bearings that it can be readily raised and lowered to facilitate the recovery of the amalgam.

In order to sweep the sludge from the cathode and prevent it accumulating or settling thereon, the rotating anode-arms are provided with pins of wood, etc., projecting downward close to the mercury cathode, but not so close as to disturb the latter; and to prevent centrifugal action, the inner side of the vat is provided with inward projections or baffles so as to break up the moving mass of sludge and prevent it acquiring a continuous revolving movement in the space above the anode.

I have found that for the same vat the number of revolutions of the anode which is necessary to effect a given agitation in the sludge is inversely proportional to the square roots of the numbers of the arms in the anode. The maximum speed which can be used for stirring the sludge in such large vats without disturbing the mercury of the cathode varies both with the construction of the vat and the nature of the ore, but it is considered dangerous to run the anode at a greater speed than about 10 ft. per second at the extremity of the arms.

In use the pulverized ore, water and cyanide solution are introduced into the vat, the anode rotated at the desired speed and current passed between the anode and the sludge. Every particle of ore is subjected to the action of the cyanide solution and the electric current, the gold or silver is first dissolved by the solution and then amalgamated by the mercury cathode.

626,972, June 13, 1899, Thomas Craney, of Bay City, Michigan.

Relates to apparatus for the recovery by electrolysis of precious metals in cyanide of potassium solution obtained by the cyanide treatment of ores. Within a tank is placed axially a hollow core provided with openings at the bottom communicating with the outer space in the tank; or a conduit may enter the tank from the outside, through which the solution is supplied.

The electrode forming the cathode consists of a thin metal foil, such as lead, enclosed in a fold of a suitable fabric, such as cotton cloth, leaving a margin of the lead foil projecting; the anode consists of thin sheet iron or, preferably, wire screen, similarly folded in cotton cloth, leaving a margin projecting; the two inclosed electrodes are now placed one above the other with the margin of one projecting in one direction and that of the other in the opposite direction, coiled tightly about the hollow core and making a tight fit within the tank, leaving a space below the electrodes for the distribution of electrolyte. The anode is suitably secured to a plate at the bottom of the tank connected to a circuit; the cathode marginal edge extends above and is also connected to the circuit. A number of tanks may be placed in cascade, the solution entering the top tank through the axial hollow core, passing up between the electrodes and overflowing into the axial hollow core of the tank lower down, etc. After the electrolysis the cathode may be removed by taking out the electrode roll, uncoiling and separating the lead foil from the cotton cloth folds, a new electrode roll being inserted in the tank. The gold is recovered by cupeling the lead foil or otherwise.

627,442, June 20, 1899, Louis Pelatan, of Paris, France, assignor to the General Gold Extracting Company, Limited, of London, England.

Relates to processes for treating ores containing gold or silver or both and refers to an application which became patent No. 623,822, in which is described and claimed the apparatus used with this process.

With ordinary ores equal weights of ore and water are used, and as the specific gravity of ores increases less water is used. The conductivity of the water is increased by adding salt or a similar substance. With sludge or pulp giving an acid reaction to the water an alkali such as lime or caustic soda is added to neutralize it before the operation begins. Also should the solution become acid during the operation an additional quantity of alkali is added to maintain a neutral or slightly alkaline condition.

The solvent agent, potassium cyanide, is then added in quantities from 0.05 to 0.2 per cent of the weight of water used; if other cyanides are used quantities containing a similar amount of cyanogen radicle as the potassium cyanide are employed. With some ores an oxidizing agent, such as peroxid of sodium, permanganate of potash, etc., are used to hasten

the action of the cyanogen. The addition of peroxid or sodium also serves to neutralize acid ores. With neutral or basic ores an oxidizing agent such as picric acid is used in the proportion of less than 0.05 per cent of the solution. The precious metal is extracted partly by electrolytic action and partly by the solvent action of the cyanide solution.

In the presence of silver if this element or its compound is not readily soluble in the cyanide the sludge and solution is heated to between 80 deg. and 100 deg. C., sodium chlorid or other suitable chlorid being added. A stronger current than ordinarily used with gold ores is passed through the sludge for from two to four hours, resulting in chloridizing the silver or its compounds. The temperature is now lowered to less than 40 deg. C., and a gentle current passed; potassium cyanid in quantity to dissolve the silver chlorid and the gold present is now added; an oxidizing agent such as picric acid may also be added. The silver and gold are precipitated electrolytically and amalgamated by the mercury cathode. An electric current of 1½ amp per square foot of mean electrode surface is advisable, but not less than 2 amp-hours per ounce of silver dissolved in the sludge should be used.

BOOK REVIEWS.

A Brief Laboratory Guide for Qualitative Analysis.. By **Arthur E. Hill,** Ph.D., Associate Professor of Analytical Chemistry, New York University. 12 mo., 80 pages. Price, $1. Easton, Pa.: Chemical Publishing Company.

This is written as a guide to the briefest possible course in qualitative analysis, intended chiefly for civil engineering students. Confidence in the scheme is justified by the fact that the author has used it six years in the laboratory and achieved satisfactory results with students who devoted eighty-five hours to the laboratory work and fifteen hours to lectures. But Dr. Hill attempts too much for the limited time at his disposal; the explanations given (in fine print) are too technical (and often too hypothetical) for his class of students and would be much better understood and more useful if made simpler and from a more general standpoint. Nevertheless, under skillful supervision, we do not doubt that students using this little book learn a good deal of qualitative analysis.

Die Elektrochemische Industrie Frankreichs. By **M. R. Pitaval;** translated into German by Dr. **Max Huth.** 16½ x 25 cm. 114 pages, 35 illustrations. Price 8 marks. Halle: Wilhelm Knapp.

An interesting review of the electrochemical industries of France, rather padded in spots, to keep up appearances. The most important parts are 15 pages on the chlorine industry, 22 pages on calcium carbide, 18 pages on fixation of atmospheric nitrogen, 15 pages on the production of aluminium, and 33 pages on electric furnace steel and ferro-alloys.

While the work is in many places carelessly written, and must in consequence be read critically, yet there are items of information contained in it, here and there, which have not been published before, and which may prove valuable to persons particularly interested.

* * *

Das Hydrosulfit. By Dr. **Karl Jellinek.** Part I: Physical Chemistry. Part II: Inorganic, organic and technical chemistry. 16 x 25 cm., 188 and 230 pages; price 6 marks each part. Stuttgart: Ferdinand Enke.

These two books form vol. XVII and XVIII of Dr. Herz's "Sammlung chemischer und chemisch-technischer Vorträge." The first part has for its object "to illuminate from the physico-chemical standpoint the properties and reactions of this most useful class of salts, which are so easily decomposed, so energetic as reagents, and therefore useful to such a high degree in the dyeing and textile printing industries." The amount of information gathered together on this one topic is remarkable and must prove invaluable to all technologists using this class of salts. Electrochemists will be particularly interested in a 25-page chapter on its electrolytic production from bi-sulphites.

In the second part the author regrets that practical details of its manufacture have not been published, and that he is forced to give extracts from patents as the only available information.

The various properties and uses in inorganic chemistry are given systematically, but probably the most valuable part of the whole work is the 46 pages devoted to the reactions of these salts on organic compounds, the basis of their large use in the organic chemical industries.

* * *

The Hydrometallurgy of Copper. By **Wm. E. Greenawalt,** C. E., B. S. Part I: Roasting. Part II: Hydrometallurgical Process. 15 x 23 cm. (6 x 9 in.), 504 pages, 112 illustrations; price $5.00 net. New York: McGraw-Hill Book Company.

The author very properly gives a large space, 155 pages, to roasting processes, because of their importance in preparing sulphide ores for leaching. The roasting to copper sulphate, the most important desideratum for subsequent leaching, is, however, much too meagerly handled, scarcely more being said on this head than the sentence: "For a sulphatizing roast, the temperature should not exceed 650 deg. C." The circumstances call for a detailed discussion of the influence of temperature, quickness of heating, length of roasting, effect of other sulphides, effect of addition agents (*e. g.* $FeSO^4$), nature of gangue, etc., on the per cent of copper convertible into sulphate by roasting.

The real leaching processes are handled at length and in general quite satisfactorily. One hundred pages are given to the chemical-alkali processes, and eighty pages to electrolytic processes. The treatment is fair and satisfactory. Other chapters deal with the extraction of gold and silver from copper ores, treatment of zinciferous ores, treatment of copper-nickel matte, working up of bluestone, power data and economic considerations.

We are fortunate in having such a desirable addition to our abundant English copper literature; it is a useful, timely, and valuable compilation.

* * *

A Text-Book of Rand Metallurgical Practice. Vol. II. Design and Construction of Plants: Transport of Materials. By **C. O. Schmitt.** 6¾ x 9 in. (16 x 22 cm.). 438 pages, 455 illustrations. Price, $6.50 net. Philadelphia: J. B. Lippincott Company. London: Charles Griffin & Company, Ltd.

Part I, written by eight different experts, describes the geology, mining, milling, chemistry and operation of the cyanide process on the Rand. This volume is written entirely by Mr. Schmitt. It describes sorting and breaking plant, crushing plant, amalgamating plant, clean-up apparatus, cyanide plant, purer supply and transportation of materials. Electrical precipitation plant is omitted, from which we infer that it has gone entirely out of use on the Rand. The book is intensely practical, and may be fairly called a model of description of metallurgical construction.

* * *

The Technical Analysis of Brass and the Non-Ferrous Alloys. By **W. B. Price** and **R. K. Meade.** 5 by 7½ in (12½ x 19 cm.). 267 pages, 17 illustrations. Price $2.00 net. New York: John Wiley & Sons.

The book describes the analytical determination of 16 metals occurring in common alloys, and then the analysis of 16 of the commonest alloys. In brass, the separation and determination of Sn, Pb, Al, Fe, Mn and P are given, in addition to Cu and Zn. Bronzes, nickel alloys, babbitt metals, solders and light aluminium alloys are handled separately; also, at the end, the analysis of commercial zinc and copper.
